In the case of a moraine-dammed lake, when the dam consisting of till or glaciofluvial deposits is breached and the lake is drained, a deep channel (spillway) is formed. In the absence of a bedrock, the channel reaches the lower levels of the lacustrine basin, extending onto its floor. Its scarp slopes gently due to colluviation of the unconsolidated material, and it is lined with blocks, which are sometimes quite large, from scouring of the surrounding material. This debris rests on till or bedrock.

A depositional landform is almost always associated with the breach. Immediately downstream of the moraine, an alluvial fan forms a slightly rounded cone. In the axis of

Lake Outbursts, Table 3 Typical features of glaciofluvial landforms resulting from glacial outbursts

Geomorphology	Associated forms and sediments
Dry glaciolacustrine basin	Slide scars and gullies Channels in basin floor Till-derived block fields Erosional scarp Abandoned dendritic drainage network
Breached morainic dam	Breached frontal moraine Deep channels Erosional scarp Coarse-grained alluvial fans Till-derived block fields
Erosion notches	Erosional scarp Till-derived block fields Slide scars and gullies on scarps and slopes Boulder bars or block levees Block fields (depositional) Coarse-grained alluvial fans
Outburst deposit	Continuous terraces or terraces remnants Erosional scarp Rectilinear or braided channels Giant current ripples Kettles Frontal scarps Sand spits Streamlined and rounded mounds
Erosional terrace	Rectilinear or braided channels Erosional scarp Till-derived block fields
Fine sediment bars and islets	Deltas Braided channels Streamlined and rounded mounds
Erosion forms in bedrock	Channels Cataracts Giant kettles Grooves

the breach, it can be eroded by subsequent fluvial action. However, its distal portions are well preserved. This alluvial fan consists of coarse-grained angular to subrounded sediments, depending on the nature of the materials composing the floor of the lacustrine basin and the dam. These materials have no sedimentary structure since they are very rapidly deposited in a mixture of water, mud, and debris of all sizes. However, they can display layering and very distinct graded bedding (from blocks to sand over a span of 200–300 m) and overlie a variety of unconsolidated formations (till, glaciofluvial deposits, etc.).

Erosion notches

Erosion notches in unconsolidated materials, occurring successively from upstream to downstream in sections with steeper slopes, are characteristic of glaciofluvial landforms resulting from glacial outbursts. They are evidence of the erosional power of glacial outbursts and

that their magnitude significantly exceeds the competence of fluvial systems. These erosion notches are very variable in length and width and form rectilinear or slightly curved corridors. They are deeper and narrower in steeply sloping sections and shallower and wider on gentler slopes. In some sections, all unconsolidated material has been totally washed away down to the bedrock, which can even be marked by grooves caused by the displacement of large blocks.

Most of the time, where the notches occur, glaciofluvial accumulations are swept away and erosion reaches the underlying till. The notches are bordered by the now sloping scarps, resulting from colluviation of unconsolidated material. The floors of the notches are planar and lined with coarse-grained material, forming till-derived block fields, which are usually matrix free. Presumably, however, various sources of sediments, due to colluviation of notch scarps or to subsequent fluvial action, could produce considerable inflows of finer material in certain areas of these block fields.

Other forms, frequently associated with these notches, can also be identified: landslide scars or gullies in the scarps, depositional block fields and boulder bars.

In sections where erosion notches incise thick unconsolidated formations, the scarps display many slide scars. The same is true in the narrow sections of valleys, where slides and gullies occur. In both cases, they form rectilinear scarps perpendicular to flow. They are very variable in size and shape and never have accumulation rims at the base, since the debris is carried away by the waters of the glacial outburst.

Immediately downstream of the erosion notches, specifically at knickpoints, blocks from upstream blanket the surface. These blocks are included in a matrix of fine sediments, also from upstream, and overlie various unconsolidated formations or the bedrock.

Block levees, consisting of piles of blocks, occur downstream of the erosion notches at the top of the scarps. They form long crests, variable in height and width.

Glacial outburst deposits

Glacial outburst deposits and the forms associated with them represent, with erosion notches, one of the main characteristics of glaciofluvial landforms resulting from glacial outbursts. They are evidence of rapid emplacement in a very high-energy fluvial environment, corresponding to the outburst's flood wave. They are mainly distinguished by the nature and arrangement of the sediments composing them. The sediments come from eroded surfaces upstream, including moraines, glaciofluvial deposits, and other unconsolidated formations. In general, they are coarse grained and contain a small percentage of particles less than 2 mm in diameter (Figure 3). They have no apparent sedimentary structure and are very poorly sorted. On the other hand, the sediments can be sandy and have large-scale cross-bedding. These accumulations usually cover large areas, blanketing various unconsolidated formations, and range from a few dozen centimeters to several meters in thickness.

Lake Outbursts, Figure 3 Typical glacial outburst deposits in Laurentian Hills, Québec. (Photo: A. Robitaille.)

The outburst deposits are emplaced in flat to gently sloping sections of the fluvial corridors and totally blanket the surface. In general, from the outset of the lake's drainage phase following the outburst flood wave, they are carved in such a way that they form terraces. Seen from above, these accumulations have several characteristics specific to outwash, such as relatively planar topography sprinkled with kettles, terraces, and rectilinear or braided channels (Figure 4). They also have multiple marks of subsequent fluvial erosion (meanders, scarps, etc.). However, their surface shows depositional forms usually associated with glacial outbursts: frontal scarps, sand spits, and current ripples.

The frontal scarps abruptly delineate the downstream extremity of the outburst deposits. They are oriented perpendicular to the direction of flow and have a sinuous, gently sloping front, whose height is comparable to the thickness of the deposits.

The sand spits occur downstream of large blocks or other obstacles to the flow. They vary in length and thickness, depending on the size of the obstacle. They are streamlined and can include sedimentary structures reflecting high fluvial energy, such as antidunes.

The giant current ripples consist of a succession of asymmetric mounds, comparable to the smaller ones commonly observed on streambeds. They vary considerably in size and composition, depending on the power of the outburst. They can be up to a few meters high and several dozen meters apart. They generally consist of poorly sorted sand and gravel.

Erosion terraces

Erosion terraces are formed on the initially convex and sheltered banks of the fluvial corridors. The outburst flood wave scours the surface first, and then the water draining

Lake Outbursts, Figure 4 Braided channels on the Markarfljot River after the 2010 Eyjafallajökull eruption, Iceland. (Photo: A. Robitaille.)

from the lake carves deep channels into a portion of the surface. Their topography is planar, sprinkled with flood-scoured blocks, and displays several characteristic forms such as rectilinear or braided channels. The former are generally short and shallow and are sometimes filled with poorly sorted sand and gravel. The latter wind through the many bars and islets carved into the till.

Fine-sediment bars and islets

Bars and islets composed of fine sediment (sand, gravel) usually occur in the distal portion of the fluvial corridor, where the water's transport capacity is considerably reduced. The sediment can be deposited in a lake or on

a very large flat surface along the fluvial corridor, but is generally deposited near the mouth. This type of sedimentation can lead to the formation of deltas or can cover marine sediments.

Fine-sediment bars and islets usually consist of sand and gravel. They are poorly sorted, but may display some layering. Their sedimentation environment is subaqueous or subaerial. Seen from above, they form a field of bars and islets intersected by braided channels. These fluvial forms are streamlined in the direction of flow and have rounded centers.

Erosion forms in bedrock

Erosion forms in bedrock result from very powerful erosional agents, such as those related to mega glacial outbursts, and affect bedrock surfaces that are not very massive and relatively brittle. The forms consist mostly of cataracts, deep channels, giant kettles, and grooves.

Conclusion

Several catastrophes in the past few centuries have prompted governments and international organizations to set up monitoring networks. In the context of global warming, which is liable to increase the number and frequency of glacial outbursts, the methods used to monitor the behavior of glacial lakes and glaciers have been refined, and it seems to be increasingly appropriate to study the effects of glacial outbursts along inhabited or developed fluvial corridors.

The geomorphological impacts of glacial outbursts highlight their great erosional power and transport capacity. They are capable of transforming and remodeling some or all materials located in the fluvial corridors over very great distances. The compilation of studies relating to glacial outbursts all over the world and the detailed study of the geomorphological impacts of the breaching of artificial dams have made it possible to identify the characteristic features of typical glaciofluvial landforms. This has led to the classification of erosional and depositional forms associated with mega outbursts, which shaped huge territories at inland margins in the past, and with outbursts that still occur today in alpine and northern regions. A landform with a particular pattern cannot only be used to reconstruct past events associated with glacial outbursts but also to try to predict the geomorphological impacts of future outbursts.

LAKE RESTORATION

Martin Søndergaard¹, Erik Jeppesen¹, Henning S. Jensen²
¹Department of Bioscience, Aarhus University, Silkeborg, Denmark
²University of Southern Denmark, Odense, Denmark

Definition

Lake restoration is a broad term used for different techniques aiming to bring a lake back to or closer to anthropogenically undisturbed conditions. Usually, lake restoration refers to methods used *inside* the lake, but sometimes it also refers to measures taken *outside* the lake such as reduction of the external nutrient loading by improved waste water treatment.

Introduction

The vast majority of lake restoration projects have been conducted to combat eutrophication. However, lake restoration has also been used in other contexts, for instance to counteract acidification in soft water lakes (a topic not included here). Eutrophication of lakes due to high nutrient loading (especially phosphorus) has been the paramount environmental problem for lakes worldwide for the past approximately 50 years (Carpenter et al., 1999).

Lake Restoration, Table 1 Most commonly used lake restoration methods to overcome eutrophication

Methods	Main principles and <i>possible problems</i>	References
<i>Physical methods</i>		
Sediment dredging	Phosphorus rich sediment is removed to reduce the internal loading of phosphorus. <i>Relatively expensive method. Disposal sites needed</i>	Van der Does et al. (1992); Annadotter et al. (1999)
Dilution/flushing	The lake is flushed with nutrient poor water to decrease phosphorus concentrations in the lake water. <i>Depends on the availability of large amounts of nutrient poor water</i>	Jagtman et al. (1992); Welch and Patmont (1980)
Water level manipulation	Increased water level decreases the risk of resuspension of sediment in shallow lakes. Decreased water level increases the growth potential of submerged macrophytes. <i>Not always easy to manipulate water level or to get permission to do so</i>	Chow-Fraser (2005); Blindow et al. (1993)
Hypolimnetic withdrawal	To increase the outflow of phosphorus, the lake water outflow is redirected through a pipe to the hypolimnion where phosphorus accumulates during summer stratification in deep lakes. <i>The outlet of nutrient rich and may be anoxic water may create problems for downstream water bodies</i>	McDonald et al. (2004); Nürnberg (2007)
Macrophyte harvest	Nuisance growth of macrophytes is removed to improve conditions for boating and fishing. <i>If growth conditions are favorable, the macrophytes will soon return</i>	Pieterse and Murphy (1990); Olson et al. (1998)
<i>Chemical methods</i>		
Hypolimnetic oxygenation	Oxygen (or air) is led to the hypolimnion of deep lakes to increase redox conditions and sorption of phosphorus. <i>Long-term treatment (>10 years) is often needed and, still, permanent effects are difficult to obtain</i>	Gächter and Wehrli (1998); Liboriussen et al. (2009)
Phosphorus inactivation	Salts of aluminum, iron, calcium, or other phosphorus-binding agents are added to the water and/or the sediment to decrease the internal loading of phosphorus. <i>Aluminum is toxic at low and high pH which makes it difficult to use in soft water lakes or in lakes with high pH</i>	Welch and Cooke (1999); de Vicente et al. (2008)
Nitrate addition	Nitrate is added to the sediment to oxidize the organic matter, decrease the future oxygen demand, and increase phosphorus sorption. <i>Nitrate addition is problematic in nitrogen-limited lakes</i>	Ripl (1976); Søndergaard et al. (2000)
<i>Biological methods</i>		
Removal of zooplankton-eating fish	Zooplankton- and/or benthic invertebrate-eating fish are removed to increase the number of large zooplankton and their grazing on phytoplankton. <i>Permanent effects may be difficult to obtain</i>	McQueen (1998); Søndergaard et al. (2008)
Stocking of predatory fish	Fish-eating fish are added to decrease the number of zooplankton-eating fish and improve zooplankton numbers and phytoplankton grazing. <i>Correct timing of stocking is crucial to achieve effects</i>	Benndorf (1995); Skov and Nilsson (2007)
Stocking with herbivorous fish	Plant-eating fish (grass carps) are added to reduce excessive growth of submerged macrophytes. <i>Phytoplankton takes over instead of macrophytes and creates turbid water</i>	Hanlon et al. (2000); Shireman and Maceina (1981)
Macrophyte transplantation and protection	Submerged macrophytes are established and protected from plant-eating birds or fish to maintain high macrophyte coverage. <i>Relatively large areas of protected macrophytes are needed</i>	Lauridsen et al. (2003); Qiu et al. (2001)
Introduction of mussels	Mussels are introduced to increase the filtration of the water and create clearer water. <i>Often zebra mussels (<i>Dreissena polymorpha</i>) are used, but this species is also invasive and may reach very high densities with negative biological and physical consequences</i>	Roy et al. (2010); Gulati et al. (2008)

Eutrophication has led to turbid water, blooms of (often toxic) cyanobacteria, loss of biodiversity, and many other changes in biological structure and functioning (Jeppesen et al., 2000). During the past decades measures have been taken in many parts of the world to reduce external nutrient loading via improved waste water treatment or diversion of nutrient rich inlets. However, particularly in developing countries nutrient loading is still increasing and the worst problems may not yet have occurred (Le et al., 2010).

Furthermore, even after a reduction of the external phosphorus loading the effects obtained may be unsatisfactory. This may reflect that the external nutrient loading

reduction has been insufficient with the result that phytoplankton is not adequately limited by nutrients. However, the lack of success may also be due to chemical or biological resistance factors inside the lake preventing or delaying improvements. Chemical resistance is caused by the release of phosphorus from a pool accumulated in the sediment when loading was high. Depending on the loading history and release mechanisms, this internal phosphorus loading typically persists for 10–15 years after the loading reduction until new equilibrium conditions are established (Jeppesen et al., 2005). Biological resistance can emerge through several biological elements which do not respond immediately to reduced loading, the

main factors are: (1) the fish community, which at increasing nutrient concentrations increases in numbers and becomes dominated by bottom-feeding species which resuspend sediment and create turbid water in their search for food, and zooplankton-eating fish species which establish a high predation pressure on zooplankton, implying that zooplankton control of phytoplankton is low; and (2) the submerged macrophytes, which at increasing nutrient loading and enhanced turbidity disappear or become strongly reduced in abundance in shallow lakes, but often show a delayed recolonization after a loading reduction. In shallow lakes submerged macrophytes are important for maintaining stable clear water conditions (Scheffer et al., 1993).

Lake restoration methods

A number of different methods to restore lakes by combating eutrophication have been investigated throughout the world for the past 20–30 years (Moss et al., 1996; Perrow and Davy, 2002; Cooke et al., 2005). Basically they can be divided into two types: (1) physical and chemical methods which aim to reduce phosphorus availability, that is, reduce the phytoplankton biomass by nutrient limitation (bottom up control) and (2) biological methods which change the biological control of the phytoplankton, for example through increased zooplankton grazing (top down control). Table 1 gives an overview of the most commonly used lake restoration methods, the principles behind, potential problems, and selected references for further information.

Results, recommendations, and future challenges

So far, most experience with lake restoration is established for northern temperate regions, although in recent years lake restoration has attracted increasing attention also in warm countries. Generally, most reported restoration initiatives have led to improvement, sometimes only in limited parts of the ecosystem, however, and the longevity of the improvements varies from a few months to more than 10 years. Only few restoration projects exist that document effects for more than a few years following the intervention.

An important prerequisite for successful restoration is prior knowledge of the lake and its catchment before planning and conducting the intervention. In particular, focus should be directed at external nutrient loading. If this is too high then long-lasting effects of restoration cannot be expected and the lake will sooner or later return to pre-intervention conditions. For shallow lakes phosphorus equilibrium concentrations below 0.05–0.1 mg P/l have been suggested, and in deeper lakes even lower concentrations are required (Jeppesen and Sammalakorpi, 2002).

In the future, lake restorations may become even more relevant because of increased demand for clean drinking water and because increased nutrient loading can be anticipated from farming areas that increase in area, due to human population growth, and expectedly will be cultivated more intensively. In developing countries enhanced

use of fertilizers and introduction of sewage systems may increase the nutrient loading. Climate changes may affect both temperatures and precipitation patterns throughout the world leading to a reinforcement of eutrophication and risk of toxic algal blooming, and the demand for successful lake restoration techniques will therefore grow (Jeppesen et al., 2009a, b).

Summary

Lake restoration can be a powerful tool to improve lake water quality, but successful restoration and lake recovery depend on a sufficient reduction of the external nutrient loading combined with sufficient restoration action. The most commonly used methods include addition of phosphorus sorption agents such as aluminum and biological methods such as removal of zooplankton-eating fish. New and improved lake restoration methods are developed and tested continuously.

LAKE SEDIMENTS

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Introduction

Lakes receive a wide assortment of suspended materials from rivers, precipitation, catchment erosion, shoreline erosion, pollution sources, and biological activities. These materials are referred to as sediments and are a very important factor in the life of a lake or reservoir. The material tends to fill lakes and reservoirs thereby restricting their intended use and, in the worst scenario, eventually converting them into marshlands or swamps.

In the case of reservoirs used for water supply, sediment may reduce the reservoir capacity to such an extent as to threaten the very existence of the reservoir which may become full and consequently unserviceable.

Organic, glacial, and volcanic sediments

Sediments vary according to the origin of the lakes. Glacial or glacial-type lakes receive many different

materials from rivers and shores which range from large boulders, rocks, pebbles, and coarse sands to fine sands, silts, and clays. In addition, organic debris resulting from eutrophic processes in the lake settles to the bottom and mingles with the inorganic sediments.

Lakes of volcanic origin are normally more rocky than glacial type lakes and contain only limited quantities of fine silt material. Volcanic ash is generally more prevalent in the bottom sediments of volcanic lakes and is useful in determining the age of the lake.

Opportunity is taken for the deposition of sediment to be studied and measured. If such measurements are carried out at appropriate intervals of time, total sediment load can be estimated.

Knowledge of reservoir sedimentation and its control remains limited although significant progress has been made. The study of lake and reservoir sediment control requires to be based on reliable field data or for the verification of physical and mathematical modeling.

As lakes become more eutrophic, organic deposition increases and the content of sediments increases promoting vegetation growth. This has the effect, in turn, of adding more organic material to the sediments and hastening the death of the lake. Oxygen demand also increases with increased organic sedimentation.

Reservoirs may contain substantial amounts of humus, wood, trees, and other refuse left in the flood areas during and after construction which have to be dealt along with the sediment or debris.

Rooted vegetation in lakes tend to trap sediments that are moving with currents and hold them in place particularly in the inshore areas. The dying or decaying plants add to the continued sediment buildup until finally the lake is inundated.

Movement of sediment

The behavior of sediment movement and deposition in lakes is largely dependent on wave action. In lakes, where waves are longer and less frequent than in reservoirs, the finer sediments such as sands, silts, and flocculent material are carried out into the lake by the waves and deposited in the lake bottom, some distant from the shoreline.

The coarser material, such as boulders, gravels, and coarse sands are left in the inshore areas. In reservoirs, which may experience short, frequent, and choppy waves, the finer materials are generally not carried out far from the shoreline but usually remain inshore and accumulate around the edges of lakes resulting in soft, muddy, or sandy shore areas.

As lakes or reservoirs start filling with sediment, wave action tends to reduce and vegetation increases, thus hastening the sedimentation of the lake. In arid zones, sedimentation is slower but because of excessive evaporation, lakes may become saline eventually precipitating inorganic salts which settle on the lake bottom.

Sedimentation in lakes usually begins with inorganic material from land sources. However, as biological production takes place, inorganic debris forms, settles, and

combines with the inorganic components of the bottom sediments. Along with this are the man-made materials which find their way to the bottom sediment in lakes. Such material may be pesticides, metals, trace elements, and other constituents which are troublesome pollutants and cause ecological problems in lake systems. These materials may enter the biological food chain through aquatic organisms, including fish, which feed on these sediments.

Suspended sediment

Suspended solids in lake waters are, in general, finely suspended particles in insoluble material including sand, silt, clay, debris from vegetable growth, algae, chlorophyll, and other buoyant-type substances. These materials originate from shore erosion through wind and wave action, tributary inputs, biological activities, and from pollution sources. Suspended solids reduce the transparency of lake waters and inhibit the penetration of light thereby reducing the photosynthetic processes and the production of oxygen. Photosynthesis is an important source of oxygen in lakes and the quantity of suspended solids in lake waters is an important factor in the organic cycle of lakes.

Transparency test of lake water

Suspended solids may be determined directly by collecting samples for standard laboratory analyses usually while carrying out water quality analyses of the lakes or rivers in the catchment. Analyses may also be determined on-site by performing turbidity tests using standard field equipment or by carrying out Secchi disk readings at the sampling location.

Secchi disk

Secchi disk readings have been used for many years to characterize the transparency of water bodies. Readings from Secchi disks may vary according to local conditions and with the observer; hence it is difficult to compare readings from different localities and by different observers. In general, Secchi disk readings refer directly to the turbidity arising from phytoplankton rather than to the vertical extinction coefficient. It is for this reason that Secchi disk readings are useful in the determination of production rates in lake waters.

Sediment accumulation and reservoir loss of storage

Reservoirs receive sediment from upstream almost continuously and release or allowance made for release as is the case in many reservoirs such as, for example, the Three Gorges Dam in China.

It is estimated that the world annual sediment discharge to the sea is as much as 13 billion tons and as much as 2.5 billion tons are trapped behind dams annually. This could mean that the estimated 6,000 km³ of world reservoir storage could be filled on average between 1,400 and 3,600 years.

Other examples of loss of storage because of reservoir sediment accumulation include Lake Mead in the USA

Lake Sediments, Table 1 Reservoir sedimentation rates and "lifetime" of reservoir (After Kobayashi, Said, and Meybeck)

Reservoir	Total capacity 10^6 m^3	Annual sediment $10^6 \text{ m}^3 / \text{year}$	Lifetime years
729 Japanese reservoirs	17,300	40.8	395
Aswan High Dam	162,000	109.0	1,600
Lake Mead (Hoover dam)	34,900	0.33%	300
World reservoirs	6,000,000	$2-5 \cdot 10^9 \text{ t/year}$	1,400–3,600

Lake Sediments, Table 2 Loss of reservoir capacity (six UK reservoirs)

Reservoir parameter	Wessenden Head	Wessenden Old	Blakeley	Butterley	Thornton Moor	Stubden
Date of construction	1881	1835	1903	1907	1885	1,868
Catchment area (km^2)	—	15,05	—	—	5,12	1,94
Original capacity (MI)	373	486	364	1,832	795	451
Revised capacity (MI)	358	321	137	1,724	702	406
Loss of capacity per century (%)	3.7	23	75.2	7.5	11.3	8.2
Annual loss of capacity (m^3)	137	1,220	2,736	1,365	895	318
Annual area-specific loss ($\text{m}^3/\text{km}^2/\text{year}$)	—	362,66	—	—	174,87	191,58

which is losing storage at the rate of some 0.33% each year implying 300 years before it is completely filled.

In the case of the Aswan High Dam in Egypt, the mean annual sediment passing through the site prior to construction was 125 million tons of which nearly all passed during floods. After construction, it was noted that only some 2.5 million tons flowed downstream of the dam. This implied that 30 km^3 of dead storage from a total dam capacity of 164 km^3 set aside for sediments in the dam would be filled in 300 years and the whole dam filled in about 1,300 years assuming conditions did not significantly change.

It is interesting to note that since the completion of the Aswan High Dam in 1964, the estuary sand bank at the mouth of the Nile retreated at least 4 km in 30 years.

Examples of reservoir sedimentation rates are given in Table 1.

During the 1976 drought in the UK, advantage was taken to study the effect of sediment accumulation on a group of six small virtually empty reservoirs in the same catchment in the Yorkshire area. The results shown in Table 2 reveal an overall loss of capacity per century of as low as 3.7% and as high as 75% with an estimated expected life of individual reservoirs in the group of between 130 and 2,000 years.

Sediment yields, however, differ from region to region. In East and Southern Asia where about two thirds of world sediments discharge into the sea, there are many reservoirs having much shorter "life" times than the examples given in Tables 1 and 2. In Thailand, for example, a number of reservoirs built for irrigation purposes were filled soon after completion with sediments derived from deforested areas. There are a number of reservoirs in Japan, mostly smaller than 10^6 m^3 built in mountainous areas

for hydroelectric power generation that experience a rapid filling of sediment, for example, within some 10 years of completion.

Recovery of storage

The methods of recovery of silted storage include flushing and emptying, siphoning, mechanical excavation, dredging, and other methods appropriate to the location.

Flushing: This usually requires outlets at very low elevation. Factors influencing flushing efficiency include geometry of the reservoir (slope, width, length, and storage capacity), amount and composition of previous deposits, and characteristics of the incoming flow and sediment.

Favorable conditions for effective flushing include:

- Steep bottom slope, narrow and small reservoir
- Unconsolidated deposits, no gravel
- High incoming discharge
- Low outlets
- Low pool level downstream

Waste of water is often the main shortcoming of flushing operation and usually is best carried out annually, the important indicator of flushing efficiency being the water–detritus (W-D) ratio, the ratio between the volume of water wasted and the volume of deposits flushed out. For many reservoirs the ratios are in the range 20–50.

Dredging

Mechanical

To remove the accumulated sediment and restore reservoir capacity, dredging of the sediment is necessary. Dredging costs can often be one of the most important costs of

reservoir operation and, depending on the reservoir size and percentage sediment accumulation, costs can be enormous.

Mechanical dredging is the major method of removing deposits of sediment from reservoirs. It consists of excavation, transportation, and disposal of the sediment. Excavation and transportation can be implemented mechanically or hydraulically and sometimes disposal may be made downstream. Mechanical excavation usually employs chain bucket, hopper wheel, shovel, grab, dipper, or backhoe dredgers.

Hydraulic

Hydraulic dredging includes cutter suction, plain suction, wheel suction, trailing suction hopper and dustpan dredgers, electric submerged pumps, and airlift pump. The transportation is by barge, pipeline, conveyer belt, cable crane, and trucks.

Siphoning

This is a special hydraulic method of dredging and consists of two parts: a dewatering device and a flexible pipeline which straddles the dam. In practice the flexible pipeline is usually connected with bottom outlets through the dam body and the pipeline and its entrance can be moved by a towing boat.

The system is widely used in small reservoirs. An example where the method is used to advantage is the Tianjiawan Reservoir in China. There a siphoning system consisting of an operating barge and a pipeline of length 229 m and diameter 550 mm was installed in 1975 to dredge the accumulated sediment. The pipeline was connected to an outlet through the dam body.

In 1977 the runoff was $4.16 \times 10^6 \text{ m}^3$ and the incoming sediment load was $2.05 \times 10^6 \text{ m}^3$. The amount of sediment dredged by siphon was $320 \times 10^3 \text{ m}^3$ with an average concentration of 190 kg/m^3 during 695 h of operation. The rate of dredging was 460 m^3 per hour therefore giving a low dredging cost.

Other methods are used, such as civil engineering works using dry-earth excavation and transportation. In practice a combination of methods for removing deposits of sediment is often proved effective.

Disposal of the dredged material is one of the major problems encountered in dredging operation, not least of which is the cost. For example, in the Netherlands it is found that $22,000 \text{ m}^2$ surface area of the disposal sites are required for each m^3/s discharge of the dredge.

Generally, there are three options for sediment disposal:

- Back into the reservoir (removing into the dead storage or near outlets)
- Onto the land (bank, valley etc.)
- Into the downstream river, but environmental requirements have to be considered
- Bypassing (diversion) channels

In Switzerland, the restriction stipulated is that a maximum of 4% sediment by volume can be mixed with

the river water. A hopeful way of disposal is to use the dredged material for industrial, agriculture, or landfill purposes. For instance, gravel dredged material has been used as concrete aggregate and sands as construction material.

Because most dams are of recent construction, sediment accumulation has not yet reached levels that seriously interfere with operations in most reservoirs. However, as reservoirs age and accumulate sediments, both the number and size of them with serious sedimentation problems is growing. Nevertheless, at many sites with serious levels of sediment accumulation, the reservoirs are not necessarily abandoned. Indeed operators seek methods of keeping the reservoirs in service by balancing sediment inflow and outflow while maximizing available benefits. This practice maintains the reservoir's "life" and its continued operation.

The loss of all the world's reservoirs due to sediment accumulation either slowly or quickly would have catastrophic results. For this reason, civil engineering practice is often to design reservoirs that will fill with sediments slowly and have a facility for containment of designed capacity.

Survey of sediment

There are basically two methods today to assess the amount of sediment accumulated or trapped in lakes and reservoirs, including a complete measurement or bathymetric survey:

- Conventional surveying method
- Electronic distance measurement (EDM) using the Globing Positioning System (GPS)

When the conventional method is chosen, it will normally be accomplished by a combination of aerial photogrammetric and bathymetric procedures. Survey normally first takes place on completion of the reservoir prior to impounding. This provides the basis to which all future surveys are compared. The conventional method using a launch equipped with echo sounder, sextant, and theodolite although formerly used for many surveys in the past is still used especially for small lakes, but now enhanced with data processor and dedicated software.

For large lakes and reservoirs, the electronic distance measurement (EDM) satellite system is now preferred employing the GPS system with one base station to serve as many roving unit outstations as necessary and equipped with receivers and data links within a 10 km radius.

Investigation of sedimentation in lakes and reservoirs

Empirical methods

As a preliminary investigation level, the sediment inflow to a reservoir may be predicted satisfactorily by applying the measured sediment accumulation rate from a nearby reservoir or another reservoir having similar catchment characteristics. Empirical methods for preliminary judgment are used generally in small reservoirs to estimate

sediment load and surface water profile. Empirical methods of study use sediment transport information such as storage ratio and hydraulic characteristics of inflow.

Mathematical model

Mathematical modeling of reservoir sediment is based on the principles of fluid mechanics, equations of motion, and continuity for water and sediment flow over a mobile bed supplemented by auxiliary equations of river sediment transport. The equations are solved under initial boundary conditions by numerical solution with simplified assumptions. Because of the diversity of sediment transport equations, numerical techniques of empirical coefficients are used.

Models are based on empirical field data of sediment transport information of rivers and existing sediment data on heavily sediment-laden rivers. However, as models rely on reliable empirical data, a properly developed and calibrated mathematical model can be used to good effect to analyze time-dependent behavior of reservoirs, and present a more complete picture of sedimentation processes including special conditions imposed by sediment sluicing and flushing operations.

Mathematical models have advanced rapidly in recent years and are generally used with confidence. However, a mathematical model often contains many empirical coefficients determined only by calibration against observed field data. A successful mathematical model addresses the following aspects:

- A knowledge of the reservoir and river to be modeled
- Reliable equations
- Suitable methods of numerical solutions

Most of the models used are classified by the terms 1-D and 2-D. It has been the practice to use model 1-D for narrow reaches and 2-D for wide reaches.

Physical model

Physical modeling has been extensively used for reservoir sediment studies for many years in some of the world's largest physical laboratories. The main questions arising concern the size and the scaling which is increasing especially in connection with important large-sized reservoirs. For example, in studies for the Three Gorges Dam on the Yangtze, a total of nine physical models were built to simulate six key reaches of total length 230 km. The horizontal and vertical scales were respectively 1/250–1/300 and 1/100–1/125. The model sediment in these models included polystyrene, bakelite, coal powders, and crushed walnut shells.

A great deal of valuable information was obtained on the prediction of sedimentation to the design of the project.

An important development is to combine physical and mathematical models and the feedback loops which exist between them. A mathematical model may be used, for instance, to provide inflows and boundary conditions for a physical model and vice versa. Also the result and

process of each may be complemented and verified. The enormous cost of physical models can usually only be supported in combination with a joint project.

Conclusion

Most river reaches are sensibly in balance with respect to sediment inflow and outflow. Dams or lakes may alter this balance and all impounded water formed by dams on natural water courses are subject to some degree of accumulation of sediment inflow and deposition which may affect this balance.

Sediments vary according to the origin of the lake and to the sediments brought down by rivers. In some cases, the economic and environmental damage of the accumulation of sediment in reservoirs can be enormous in both cost and remedial action. The sediment inflow to a reservoir is that part of the product of all erosion mechanisms at work in the catchment which enter the stream system and are transported to the lake or reservoir. In lakes this may be a small part of the total erosion ongoing in the catchment but in the case of reservoirs the financial cost can be high with respect to the loss of the value of water and the cost of remedial action which may be significant.

LAKE SHORE NOMENCLATURE

Léo Provencher, Jean-Marie M. Dubois
 Département de Géomatique Appliquée et CARTEL,
 Université de Sherbrooke, Sherbrooke, QC, Canada

Introduction

A recognized geomorphological nomenclature of the coastal zone is in use for a long time (Ottman, 1965;

Zenkovich, 1967; Ellis, 1978; Davis, 1982), which is not the case for fluvial and lacustrine milieus. In fact, for these milieus, the specialists have developed a specific nomenclature for each discipline. But the coastal or the fluvial nomenclature is too often applied without distinction to the lacustrine milieu. To our knowledge, the only book entirely dedicated to lacustrine terminology is the one of Veatch and Humphrys (1964), but it is incomplete. As the three mentioned milieus are submitted to different conditions and processes, their nomenclature should be different (Mailhot et al., 1985).

Particularities of the coastal, lacustrine, and fluvial milieus

The coastal and estuarine zones, the lakeshore, and the valley bottom are terms designating the shore zone, which is the area on both sides of the shoreline under the influence of currents, overflow waters, tides, or waves. The shore zone invariably includes terrestrial and aquatic parts which are under the influence of different water levels. The lower and the upper limits of the shore zone are delineated by extreme water levels.

Mailhot et al. (1985) have proposed a specific nomenclature for coastal, lacustrine, and fluvial milieus which are affected by specific dynamics. The coastal milieu is characterized by daily fluctuations of the water by tides and by important wave amplitude mainly during spring tide and storms. The lacustrine milieu is characterized by seasonal fluctuations of water level and by the wave action limited by the wind fetch. This wind fetch rarely allows the formation of important waves except for major lakes like the Great Lakes. Finally, the fluvial milieu is affected by the discharge which generates the water flow and also by the fluctuations of the water level in relation with the floods. The height of the floods depends on the watershed morphology and on the hydrologic regime.

The nomenclature of the shore zone is complex, considering the fact that the specialists of each discipline have developed their own vocabulary. Thus, geomorphologists, biologists, limnologists, planners, and lawyers name differently the components of the shore zone in accordance with their knowledge and concern in relation with the considered milieu. By example, the limnologist defines the lower limit of the shore zone in regard with the lightness. The decline of the lightness with the water depth influences the distribution and the growth of aquatic plants (Wetzel, 1983). On the other hand, the geomorphologist defines this limit in regard with the wave action which is responsible of the formation of the drop-off in a lake.

The basic elements used to create the different nomenclatures are:

- Terrain forms resulting from the currents and wave action (geomorphologists)
- Trophic stage of the aquatic milieu (biologists and limnologists)
- Potential use of the shore zone (planners)
- Laws and regulations related to the private property and environmental protection (lawyers)

Lake Shore Nomenclature, Figure 1 Lake shore nomenclature for geoscience specialists.

Lake shore geomorphological nomenclature

The terrestrial milieu of lake shore zone corresponds to the shoreland and to the valley side, and the lacustrine milieu corresponds to the lacustrine beach. In the shore zone, three geomorphological divisions are related to the water level fluctuation: backshore, emerged beine, and submerged terrace.

The limits of these divisions are respectively the overflow level related to exceptional floods, the annual flood level occurring at the period of highest precipitations or at the spring melt out of the snow cover, the mean water level, and finally the foot of the drop-off. The shoreline, dividing the lacustrine and aquatic milieus, corresponds to the high water level related to usual water level.

Lake shoreline

The lake shoreline corresponds either to an erosion talus or to a depositional form (Figure 1) in relation to the wave action budget on each part of the lake periphery.

Excluding karstic and endorheic lakes, which have variable levels, the lake shoreline is generally stable at the human observation time scale because it is under the control of the outlet. In natural conditions, the lowering of the

outlet is gradual or in jerks and results only from the regressive erosion processes. On the other hand, the rare cases of natural heightening of the outlet result from lava flows, mass movements, glacier surges, beaver dams, etc. The more frequent cases of outlet heightening are human made, like the setting of dams for hydroelectric production or the regulation of hydrologic regime of streams and lakes.

In a long-term period, the shoreline can be modified by sediments deposition (deltas), by the encroachment of the vegetation (peat bogs, marshes) caused by lake eutrophication or by man-made encroachment.

Lake shore terrestrial milieu

The terrestrial milieu of the shore zone includes the backshore beyond which extends the backland, if the slope of the surface is similar to the slope of the backshore, or the valley-side, if the slope becomes steeper.

The backshore is only slightly influenced by the waves' action. The low occurrence and short period of overflow do not allow any particular shaping of this part of the shore zone. A microtalus or high-water marks made of vegetation debris can occur at the overflow limit (Vachon *et al.*, 1997).

Modified after Wetzel (1983)

Lake Shore Nomenclature, Figure 2 Lake shore nomenclature for biologists and limnologists.

If the overflow water is muddy, the surface of the backshore can be silted.

The backshore is often humid because it corresponds totally or partially with the resurging area of the phreatic water table.

Lake shore lacustrine milieu

The geomorphology of the aquatic part of the shore zone is different according to the presence of erosion or deposition processes. In an erosion situation, a bluff replaces the emerged beine occurring in a deposition situation.

In an erosion situation, the aquatic part corresponds to the submerged terrace divided in three parts: the bluff, the beine, and the drop-off. The bluff, resulting of wave action, is located between the annual flood level, corresponding to the shoreline, and the mean water level. The beine corresponds to an erosion surface in its proximal part and to a deposition surface in its distal part. The beine is located between the mean water level and the

inferior limit of the wave action corresponding to the upper limit of the drop-off. The drop-off is built by sediments carried by waves towards the lake bottom.

In a deposition situation, the aquatic part includes the emerged beine and the submerged terrace. The emerged beine is located between the annual flood level, corresponding to the shoreline, and the mean water level. The emerged beine results from deposition processes which extend to the submerged terrace. The submerged terrace includes the beine and the drop-off, similar to the erosion situation. The only difference is that the beine is the result of sediment deposition.

Biologists' and limnologists' nomenclature

Biologists and limnologists use a different nomenclature for the lacustrine milieu. This nomenclature is based on zonation of vegetation (Figure 2).

The delimitation of the different zones is justified by the distribution of vegetation types in accordance with the

Modified after Veatch and Humphreys (1964), Loup (1974), Dubois (1979), Mailhot *et al.* (1985), Greenwood (2005) and Chrzastowski (2005)

Lake Shore Nomenclature, Figure 3 Comparative nomenclature of lake shore, coastal zone, and valley bottom.

decline of the lightness in the water (Hutchinson, 1967). The vegetation of the “littoral” milieu changes gradually from riparian species between low and high waters (eulittoral) to rooted species which are emergent, floating-leaved, or submerged in the infralittoral. The vegetation of the pelagic milieu is mainly composed of different algae species.

The nomenclature used by biologists and limnologists is completely different from the one used by geoscientists.

In particular, we notice that biologists and limnologists improperly use the coastal term “littoral” instead of lake shore.

Planners’ nomenclature

The nomenclature used by planners is limited to the difference between dry beach and wet beach (Veatch and Humphrys, 1964). The limit between the two zones

Lake Shore Nomenclature, Figure 4 Reservoirs zonation terminology.

approximately corresponds to the mean water level, corresponding to the shoreline. This elementary nomenclature is justified by the different recreational activities practiced in the terrestrial and aquatic milieus (Provencher and Thibault, 1976).

Comparative nomenclature of lake shore, coastal zone, and valley bottom

The shoreline is the only common term used, with the same signification for the three milieus (Figure 3).

In fact, in each milieu, the shoreline corresponds to a high water level: the annual flood level for lakes and rivers and high tide level for the coast. Almost all the other terms are specific to each milieu as the geomorphologic and ecologic processes are different.

Transition situations exist between the fluvial and lacustrine milieus as well as between fluvial and coastal milieus. It is particularly the case for reservoirs where the elevation of the water level results in the widening of the downstream part of tributaries to create a fluvio-lacustrine zone (Figure 4).

In such cases, the terminology will gradually change from lacustrine to fluvial.

LAKE SURVEYING

Peter Ulriksen
Teknisk Geologi, Lunds Universitet, Lund, Sweden

Synonyms

Lake bathymetry; Lake morphometry

Definition

Profiling: A survey that provides a cross section along a line across a lake.

Mapping: A survey that covers a horizontal area, just like a conventional map.

Bandwidth: The frequency range used by the instrument. A larger bandwidth provides better range resolution.

Aperture: The size of the transducer measured in wavelengths. In that respect a large transducer generates a narrow beam-width.

Penetration: The capacity of a sonar to reveal sedimentary features below the bottom.

Footprint: The area on the bottom which is illuminated by the sonar and may produce an echo.

Introduction

The original method for lake surveying is by using a rope and a weight. Often this rope carries knots at regular intervals. The pseudonym “Mark Twain” refers to the second knot on the rope equal to a depth of two fathoms, the once necessary navigation depth for a steamer on the Mississippi River. Positioning on lakes could be made by sight-lines to pairs of objects ashore, which permits very precise navigation along a straight line. Another possibility for positioning is to make measurements from holes through the ice, if such conditions exist. Today lake surveying is usually done with different types of sonars, transmitting and receiving reflected acoustic energy.

This equipment is the same as is used for surveying of the sea. Navigation and positioning is left to the Global Positioning System (GPS) or any of the other similar systems based on satellite data. The advent of the digital computer facilitates mapping of lakes in that it is not necessary to measure in a regular grid to facilitate manual interpolation. Any pattern will do and the navigation plot will tell the operator that all parts of the lake have been surveyed.

Lake surveying differs from marine surveying in that lake water is less conducting than seawater and thus in many cases permits the use of radio waves as a complement to acoustic and light-waves that work in both types of water.

In addition to the physical principle used, it is also relevant to separate the survey methods into profiling and mapping methods. In the profiling method, the depth of the water and possibly the structures of sediments and even rock are measured along a line, giving a 2-D output (length, depth), while in the mapping method the output is in 2-D (length, width) or in 3-D (length, width, and depth). The dimensions referred to here are the geometrical ones. In addition there is a radiometric dimension, which is the strength of the bottom echoes. There may also be a spectral and a temporal dimension in survey data. A spectral dimension occurs if the transmitted pulse is of a wideband nature and a temporal dimension is created by repeating a survey along the calendar time axis. Mapping can of course also be performed by surveying many parallel profiles.

All described methods are based on the transmission of pulses and recording of echoes emanating from objects and structures of interest to the surveyor, the echo delay generating information about range. A significant property is the beam-width radiated. It is determined by the aperture size in wavelengths. A large aperture in this respect creates a narrow beam. The illuminated part of the lake bottom is the footprint of the sonar. Any object within the footprint that has a geometric normal pointing toward the transducer will be able to generate a recorded echo.

Profiling 2-D: the echo sounder

The most common instrument for lake mapping is the echo sounder, which covers both the sonic and ultrasonic frequency ranges. A pulse is transmitted toward the bottom and echoes are recorded and presented as a profile. Such a pulse is often called a ping. Since the velocity of sound waves in water is known to be about 1,500 m/s, the recorded time of echoes can be transformed into distance by a simple operation. For more precise requirements there are special probes that can be lowered to get a velocity profile in the water column. Generally sonic instruments, which operate below 20 kHz per definition, give penetration into the sub-bottom layers revealing the structure of the sediments. A known problem is the presence of gas bubbles in sediments, which will decrease penetration of acoustic waves. Ultrasonic instruments provide higher lateral resolution of bottom surface features because the transmitted beam can be made sharper

with a similar size transducer and also the pulse length can be made shorter to provide higher vertical resolution. Only very soft bottom sediments – mud blankets with properties much like water – are penetrated with ultrasonic waves. The ultrasonic echo sounders generally operate below 200 kHz. The echo sounder can be deployed from any craft of opportunity.

Profiling 2-D: the parametric sonar

The parametric sonar takes advantage of the nonlinearity of water. If a very strong high-frequency pulse is transmitted there will be a leakage into a lower frequency range. The interesting thing with this low-frequency pulse is that it will have the same beam-width as the high-frequency pulse. A parametric sonar thus can present a precise echo from the lake bottom and surface sediments using the high-frequency echoes, while the low-frequency echoes would reveal deeper structures in the lake bottom. It is of particular interest that those two profiles, contra-intuitively, would have the same horizontal resolution. The reason for this is that the conversion from high to low frequency takes place only within the high-frequency beam. Also the parametric sonar allows low-frequency sounding to be made with rather light equipment. The minimum depth required for the parametric effect to develop is usually in the range of a couple of meters. The parametric sonar can be deployed from any craft of opportunity.

Profiling 2-D: the ground-penetrating radar, GPR

In low conductivity freshwater radar is a feasible method for bathymetry and sub-bottom profiling. The useful frequency would be about 100 MHz. The speed of electromagnetic waves in freshwater is about 0.033 m/ns. The range increases with lower frequency and lower electrical conductivity of the water. Resolution is improved with a higher frequency. Due to the nature of electromagnetic waves gas bubbles may be a lesser problem with radar than with an acoustic sounder. The GPR pulses are always of a wideband nature, which makes spectral signatures feasible to obtain, thus helping in bottom classification. For mapping sub-bottom features in deep lake water a borehole antenna can be used. It would be towed behind a boat in a cable with the antenna just above the bottom in order to reduce the attenuation in the water. A very practical feature of using radar is that profiling could be made through ice if such is present. Navigation is greatly simplified by this tactic. Obviously profiling of freshwater ice thickness is also possible with radar. For that purpose higher frequencies would be chosen. For mapping freshwater ice thickness 500 MHz could be used with the antenna installed in a helicopter. The GPR can be deployed from any craft of opportunity.

Mapping 2-D: the side-scan sonar

The side-scan sonar is, in principle, an echo sounder turned sideways, albeit with a different radiation pattern known as a vertical fan-beam illuminating the bottom

sideways. Thus the arrival time of echoes are converted into lateral distance (range) instead of vertical distance (depth) as it is in the echo sounder. The image is built up in the same way as a television image, by adding line after line to form a 2-D image, each line produced by a new ping. One dimension is created by the forward movement of the craft, the other dimension by the echo-time converted to slant range distance. In order to create an image with good resolution it is desired to project an ultrasonic fan-beam which is very narrow in the direction of travel. A side-scan sonar tow-fish, containing port and starboard transducers, is pulled in a cable behind a boat to make the trajectory smooth. By varying the tow-fish altitude over the bottom different shadow effects are obtained. A trajectory close to the bottom will generate longer shadows from objects protruding above the bottom than a higher trajectory will do. The shapes of shadows behind such objects often tell more about the objects than the direct echoes do. Depending on the frequency chosen there will be different backscattering from different types of bottoms, thus making it possible to map the extent of, e.g., rocky vs. sandy or gravel bottom. Since time is converted to slant range it cannot also be converted to depth. This means that a side-scan sonar cannot be used to measure the depth of sub-bottom features. A strongly protruding object (proud object) would be mapped closer to the sonar than the real distance. Sub-bottom features may be recorded, however, but depth would be added to range. A possible discrimination method is to use a high-frequency image to record bottom features and a low-frequency image to identify sub-bottom features in addition. The difference image would indicate only sub-bottom features. Side-scan sonars are operated from a few kHz to one MHz, with ranges between tens of meters to tens of kilometers. High-frequency systems could be deployed from any craft of opportunity.

Mapping 2-D: the sector-scan sonar

A special kind of side-scan sonar has a small side-scan transducer that rotates around a vertical axis and creates an image by plotting the echoes on a Polar Plot Indicator (PPI), just like the archetypal radar screen. This kind of sonar is often used on underwater robots for detection of objects and is normally operated above 500 kHz. The radial range may be 50–100 m. Modern systems use electronic scanning of the beam. It may be useful to lower this type of sonar through a hole in ice. Before the advent of the multi-beam sonar (see below), PPI-sonars could be used with the rotating axis horizontal and oriented in the direction of travel, in order to produce a sequence of lateral profiles of the bottom topography. Due to the high frequencies used, no penetration into bottom sediments is expected. The sector-scan sonar can be deployed from any craft of opportunity.

Mapping 2-D: the synthetic aperture sonar, SAS

In a side-scan sonar the narrow beam-width in the direction of travel is produced by having a transducer that is

long relative to the wavelength in the same direction. For very high resolution at low frequencies the length of the transducer would render the tow-fish impractically long. In order to overcome this problem the synthetic aperture sonar combines the echoes from 10 to 100 subsequent pings to computationally generate an image with range independent and very high azimuth resolution. All of the used pings must illuminate a given target, which requires a wide beam and thus, contra-intuitively, a rather small transmitting transducer is used. The range resolution is only affected by the bandwidth of the transmitted pulse, which is often a chirp, which is a frequency sweep within the ping. The reconstruction process requires very precise information about the transducer orientation for each ping, thus making it necessary to add expensive positioning equipment. The SAS requires permanent installation in a suitable craft.

Mapping 3-D: the multi-beam sonar

The multi-beam sonar can be thought of as a number of echo sounders in parallel. Each receiver covers a laterally displaced track on the bottom but there is only one ping transmitted. The unique outcome is a 3-D data set showing the bottom topography in a swath under the ship. This kind of sonar utilizes digital signal processing to form the different beams. The survey must be supported by a GPS system and a Motion Reference Unit (MRU). All information is thus geo-coded and this kind of sonar is now dominating in the production of bathymetric maps. The multi-beam sonar requires permanent installation in a suitable craft.

Mapping 3-D: airborne laser

Small water depths are often difficult to measure using a boat as a vehicle. For such situations, e.g., in the beach zone, airborne laser may be an alternative to walking around with a GPS on a stick. It works much like the multi-beam sonar but with light. A short, usually green, laser-light pulse is transmitted at different lateral angles from the nadir direction, thus producing a swath of depth measurements perpendicular to the direction of flight. For each angle a new pulse is transmitted. When many such swaths are generated along the flight track a 3-D data output is obtained. There is one echo from the surface of the water and a second echo from the bottom. The water has to be optically transparent. Special inertial and GPS equipment must be used to remove the trajectory of the aircraft and to geo-code the data.

LAKES AS ARCHIVES OF EARTH HISTORY

Barbara Wohlfarth
 Department of Geological Sciences, Stockholm
 University, Stockholm, Sweden

Synonyms

Limnogeology; Paleolimnology

Definition

The sedimentary record preserved in lakes and ancient lakes provides an archive of past climatic and environmental changes.

Lakes as archives of earth history

Lakes have existed and vanished throughout Earth's history, but their traces have been preserved in the form of sedimentary rocks, sediments, and shorelines (see "[Lake Sediments](#)", "[Classification of Lakes from Origin Processes](#)", "[Age Determination of Lake Deposits](#)"). All lakes have been and are subject to a variety of external and internal forcing variables that regulate the subsequent history of the lake, such as climate, bedrock composition in the catchment, tectonic and volcanic activity, vegetation, aquatic biota, and human activities (see "[Lakes on Earth, Different Types](#)", "[Stratification in Lakes](#)", "[Sedimentation Processes in Lakes](#)", "[Climate Change Effects on Lakes](#)"). These variables or traces of these are preserved in the sediments and sedimentary rocks and form excellent physical, chemical, and biological markers to reconstruct climatic and environmental changes using different types of analytical methods. Ancient lacustrine sedimentary rocks moreover form important hydrocarbon sources. The study of these changes in space and time is termed limnogeology and/or paleolimnology (see "[Paleolimnology](#)").

LAKES ON EARTH, DIFFERENT TYPES

Lars Håkanson

Department of Aquatic Sciences and Assessment
Institute for Water and Environment, Swedish University of Agricultural Sciences, Uppsala, Sweden

Introduction and aim

Hutchinson (1957) has discussed all major lake types, their origin, morphometric characteristics, and distribution on Earth. He differentiated among 11 major lake types that were divided into 76 subtypes. The 11 major lake types are summarized in Table 1. Most lakes on Earth appear in glacial landscapes. The aim of this short paper is to summarize the main characteristics of these major lake types, and most of these descriptions emanate from Håkanson (1981) (Table 2).

Results

As for biological species, lakes exist in three successive stages; youth, maturity, and old age. Lakes generally originate from drastic geological events, such as volcanism, earthquake, or glaciation. The relief of the drainage area and the lake basin is under ongoing alteration by exogenic forces, e.g., weathering, erosion, transport, and accumulation. Most lakes in northern Europe and North America have been influenced by the great form-creating power of the latest, but not last, glaciation. If there are no future tectonic catastrophes, all these lakes will in due course be filled up by sediments and transformed into land. The 11 major lake types on Earth are:

1. Tectonic lakes formed by movements of the deeper part of the Earth's crust, e.g., lakes form by tilting, folding, or warping, such as the Central African Rift lakes. Some of the largest lakes on Earth belong to this category. The Caspian Sea, the Sea of Aral, and other lakes from the Pontocaspian area have been separated from the sea by several land elevation events. Also the mountain-building events that created also the Alps produced lakes of this category.
2. Volcanic lakes, e.g., maars, calderas, and crater lakes, as well as lakes formed by volcanic damming

Lakes on Earth, Different Types, Table 1 Major lake types on Earth according to Hutchinson (1957)

1. Tectonic lakes, e.g., basins in faults (like Lake Bajkal and Lake Tanganyika).
2. Volcanic lakes, e.g., maars, caldera lakes and lakes formed by damming of lava flows.
3. Landslide lakes, e.g., lakes held by rockslides, mudflows, and scree.
4. Glacial lakes:
 - A. lakes in direct contact with ice, e.g., lakes on or in ice and lakes dammed by ice.
 - B. Glacial rock basins, e.g., cirque lakes and fjord lakes.
 - C. Morainic and outwash lakes, e.g., lakes created by terminal, recessional, or lateral moraines
 - D. Drift basins, e.g., kettle lakes and thermokarst lakes.
5. Solution lakes, e.g., lakes formed in caves by solution.
6. Fluvial lakes:
 - A. Plunge-pool lakes.
 - B. Fluvial dams, e.g., strath lakes, lateral lakes, delta lakes, and meres.
 - C. Meander lakes, e.g., oxbow lakes and crescentic levee lakes.
7. Aeolian lakes, e.g., basins dammed by windblown sand and deflation basins.
8. Shoreline lakes, e.g., tombolo lakes and spit lakes.
9. Organic lakes, e.g., phytogenic dams and coral lakes.
10. Anthropogenic lakes, e.g., dams and excavations made by man.
11. Meteorite lakes, e.g., meteorite craters.

3. Landslide lakes are created by mudflows, rockslides, and scree
4. Glacial lakes; there are very many types of glacial lakes, and it is often difficult to give clear-cut distinctions between glacial lakes and lakes influenced by other activities. The following main types of glacial lakes may be identified:
 - Lakes in direct contact with ice, e.g., lakes on ice or lakes dammed by ice.
 - Glacial rock basins, e.g., sub-alpine (or piedmont) lakes, cirque lakes or fjord lakes. To this category belong lakes of the English Lake District, lakes Geneva, Constance and Brienz in the European Alps, the Great Slave Lake in Canada, the fjord lakes in Norway (e.g., Mjøsa) and the Laurentian Great Lakes in Northern America.
 - Morainic and outwash lakes, e.g., lakes created by terminal, recessional and lateral moraines.
 - Drift basins, e.g., kettle lakes and thermokarst lakes.
5. Solution lakes. The famous region for solution lakes is the Karst area along the Dalmatian coast, but solution lakes exist also in Florida. The water percolation deposits of soluble materials such as limestone and gypsum may produce cavities and lakes of this type.
6. Fluvial lakes are produced by running water, e.g., plunge pool lakes, fluvial dams and meander lakes
7. Aeolian lakes are produced by wind action mainly in arid environments, e.g., deflation basins and lakes dammed by windblown sand (loess)
8. Shoreline lakes are generally created by longshore currents, e.g., tombolo lakes and spits lakes

Lakes on Earth, Different Types, Table 2 Morphometrical data for the four largest Swedish lakes (From Håkanson, 1981)

	Vänern	Vättern	Mälaren	Hjälmarén
Total area (km ²)	5,893	1,898	1,617	492.9
Open water area (km ²)	5,648	1,856	1,096	477.8
Volume (km ³)	153	74.0	14.0	2.89
Maximum depth (m)	106	128	63	22.0
Mean depth (m)	27.0	39.8	12.8	6.05
Large islands (> 1 km ²), number	20	6	43	4
Total area (km ²)	177.8	36.2	9.03	9.03
Islands (1–0.01 km ²); number	793	81	354	95
Total area (km ²)	54.7	4.65	4.51	4.51
Small islands (1–0.01 ha); number	8,772	813	1,248	963
Total area (km ²)	11.8	0.96	1.21	1.21
Rocks (< 0.01 ha); number	12,100	10,999	6,584	14,546
Total area (km ²)	0.58	0.52	0.31	0.36

9. Organic lakes are a relatively small category of lakes, e.g., beaver dams, coral lakes, or dams formed by vegetation
10. Anthropogenic lakes are formed by the activity of man
11. Meteorite lakes are created by the drastic impact on earth by meteorites

LARGE DAMS AND ENVIRONMENT

Peder Hjorth
 Department of Water Resources Engineering, Lund
 University, Lund, Sweden

Introduction

Rainfall is the most variable component of the hydrological cycle. Oftentimes, rainfall does not occur when it or where it is needed. The construction of a dam creates a reservoir where water can be stored during wet periods and saved until it is needed during dry spells.

If reservoirs are connected to form a network, they can be used to overcome some of the problems caused by the spatial variability of rainfall.

The first dams were constructed some 5,000 years ago, on the Euphrates and Tigris rivers in Mesopotamia and on the Nile in Egypt. The pace of dam construction was, however, not very fast. According to the International Committee on Large Dams (ICOLD), there were less than 500 dam at the end of the nineteenth century. Of them less than 10 could be classified as large dams. Postel (1993) claims that it was not until two centuries ago that the science of irrigation, grounded in the principles of hydraulics, took root. In 1800, an estimated eight million hectares, an area about the size of Austria, were equipped with watering facilities. A number of large projects constructed during the nineteenth century, especially in India and what is now Pakistan, brought the total area irrigated in 1,900 t about 48 million hectares.

As world population grew from 1.6 billion to more than five billion over the past 90 years, irrigation became a cornerstone of global food security. The higher yields farmers could get with a controllable water supply proved vital to feeding the millions added to our numbers each year, especially as opportunities to cultivate new land dwindled. The so called Green Revolution was based on high yielding varieties of seeds or modern varieties of seeds, as many scholars prefer to call them. They think that the term high yielding will make people believe that are high yielding under any condition. However the high yields require fertilizers and controllable water. The importance of fertilizer in this production system explains why the Green Revolution is sometimes termed the “seed-fertilizer revolution” and, in the same way, the phrase “blue revolution” has been used to point at the central role of controlled water (Karim, 1986).

In the first half of the twentieth century, the focus of river organizations was concentrated on irrigation, hydro-power, and flood protection. People believed in the “domination of Nature paradigm” and the common belief was that every drop that went to the sea was a lost drop. When people started to question this paradigm in the 1960s, they became more unhappy about the environmental impacts of large dams.

Although the first clash between dam developers and environmentalists started already in 1903 around the construction of the Hetch Hetchy Dam in Sierra Nevada, it was not until the 1970s that academics started to write about the issues. One example is “The Careless Technology” (Farvar and Milton, 1973). Here, there is a contribution by Kenneth E. Boulding, the economist who invented the concept of Spaceship Earth (Boulding, 1965).

His contribution is “A ballad of Ecological Awareness.” The first line reads:

The cost of building dams is always underestimated –
and the last three lines read:

So cost-benefit analysis is nearly always sure.
To justify the building of a solid concrete fact
While the Ecologic Truth is left behind in the Abstract.

In the ballad, he also mentions problems like farmlands and forests submerged by the reservoir, waterlogging, diminishing fish stocks, siltation, and the increasing amount of infected snails and waterborne diseases.

An emerging awareness of the environmental problems

It was not until the UN 1977 Water Conference in Mar del Plata that there was a global assessment of the state of water resources and water management. The result was quite shocking, and the result was a call for “Integrated Water Resources Management” and an upgrading of river basin organizations.

It is fair to say that it was not until after this conference that environmental and social impact assessments were included in dam project appraisals. By then, 35,000 large dams out of the 45,000 we have today had already been constructed. No wonder then that the world is faced by a host of dam-related environmental problems.

Loss of habitat

It is not just people that are displaced by the reservoirs created by large dams. Bardach and Dussart (1973) assert that “most species of large and small game have territories, home ranges, and feeding circuits associated with the main stream of a river or its tributaries.” “It is this habitat, of course, that a dam floods. Since the majority of animals cling tenaciously to their home grounds, the arrival of (the flood of waters) spells death for most territorial creatures.”

Thus, the Three Gorges project on the Yangtze River not only endangers the Chinese River Dolphin and the Chinese Alligator, but also the Chinese Tiger, the Siberian Crane, and the Giant Panda (O’Hara, 2005).

Downstream water shortage problems

Damming and profligate water use make many rivers periodically fail to reach the ocean. Examples of affected rivers are the Yellow River in China and the mighty Ganges (Hjorth, 2001).

When the Hoover Dam and Lake Mead filled, there was hardly any river water reaching the Colorado River estuary for almost 6 years (Rodriguez et al., 2001). Later,

when the Glen Canyon Dam and Lake Powell filled, there was a similar problem. Now, the Sierra Club (2000) claims that the Colorado River no longer reaches the sea and that its delta has been converted to a dry salt flat.

Another example is the High Aswan Dam on the Nile. The construction of this dam drastically changed the downstream conditions. There were no more any floods and no silt in the water. As the irrigated area was not expanded after the dam construction, farmers could apply more water to the land they were already cultivating. As a result, the return flows from the farmlands to the Nile became more salty and the Nile water became more saline (White, 1988).

It seems that much of the salinity of the Nile is deposited in the Nile Delta as the outflow to the Mediterranean has the same salinity as before the dam construction. Another effect is that the delta has become much smaller due to the lack of silt in the water. As the amount of nutrients in the water flowing into the sea has been reduced, the annual landing of the sardine fishery in the eastern part of the Mediterranean has been reduced from 18,000 t to 3,000 t. However, it is not firmly established that all of this decline can be blamed on the Aswan Dam (White, 1988).

Changes in the aquatic environment

The damming of a river generally causes important changes of the aquatic environment. As a flowing river reach is converted to a lake, many of the existing fish species may be outcompeted by other species that are better adapted to the lacustrine (lake) regime.

As the reservoir will submerge farmland, forests, and human settlements, there will be exchange processes that will impact the chemical composition of the reservoir water. This will have an impact on the selection of species that will thrive in the reservoir.

If the reservoir area is not effectively cleaned before the reservoir filling starts, the biomass on the bottom of the reservoir will start to decompose, a process that consumes much oxygen. The result is that the oxygen in the bottom layers will be used up, and there will be a production of H_2S , which is poisonous to fish. If bottom water is released from the reservoir, there may be significant fish kills downstream of the dam.

The water temperature is most likely to change as the heat exchange processes for a large and deep water body is different from that of a shallow running stream.

The fluctuating water table in the reservoir may prevent littoral areas to be used as spawning grounds. As the reservoir traps all sediments that enter it, the downstream erosion pattern will change, which may affect existing spawning grounds downstream.

Environmental flows

In their natural state, most rivers have periodical flooding events. Dams tend to eliminate these flooding events. One example is the Hoover Dam on the Colorado River. This river had experienced natural flooding before the construction of the dam eliminated the natural floods, which

imperiled many species adapted to the flooding, including both plants and animals (Schmidt et al., 1998).

Covich (1993) noted that if the water of a reservoir is used only to optimize the amount of irrigation water or hydropower production, the downstream environment may suffer great damage. This has now been widely understood, and a new research area has been developed, Environmental Flows. According to the global Environmental Flows Network (eFlowNet), environmental flows refers to water provided within a river, wetland, or coastal zone to maintain ecosystems and the benefits they provide to people (eFlowNet, n.d.).

The failure of bioengineering

Dams prevent fishes to swim upstream to their spawning grounds, and fish swimming downstream may get crushed in the hydropower turbines. The Columbia River is a case in point. It used to be the richest US salmon river outside Alaska. Now, it is almost completely harnessed with dams from the headwaters in Canada down to the Bonneville dam in the lower reaches. Together with its tributary Snake River it is a classic example of failure to solve fish-versus-dams problems.

Fishery biologists and administrators bitterly opposed the high-dam construction projects and predicted the fishery would be ruined if the plans materialized.

The engineers confidently assumed that, thanks to advances in devising fish-passage facilities at the high dam, we could “fish and power too” on the Columbia.

With 50 years of hindsight, it is easy to see that the biologists were right and the engineers wrong. Despite the expenditure of more than \$500 million in fish-ladders, bypasses and allied facilities, and a vast restocking program, much of the salmon habitat in the river has been lost and the runs of major species have greatly declined. It is estimated that, between 1960 and 1980 alone, the loss of fish was worth \$6.5 billion (Netboy, 1986).

Aesthetic or recreation values can also be an issue. The early conflict mentioned above was about the construction of the Hetch Hetchy Dam, which was primarily intended to supply water and electricity to the city of San Francisco. The problem was that it submerged the Yosemite Valley, one of the most beautiful national parks in the USA.

Waterlogging and salinization

In the irrigation perimeters served by large dams, waterlogging and salinization may be serious problems. Waterlogging is the rise of the groundwater table to levels too close to the level of the land surface. In case of saturation of the root zone with water, plant growth is harmed. Another problem is that a high groundwater table will allow water to rise to the ground level by means of capillary suction. There, the water will evaporate and leave its salt content on the land surface. According to Varma (1999), waterlogging is caused inter alia by over-irrigation, seepage, lack of subsurface drainage, etc. Such land turns saline or alkaline and ultimately becomes unfit for cultivation. This is a serious

problem, since during the past two decades, the trend has been for the reduction of the acreage of irrigated land.

With a dam project for irrigation, there typically comes a grid of irrigation canals. Thus, one frequent reason for rising groundwater tables is that water is leaking from distribution canals into the groundwater.

Waterlogging could also be caused by irrigation per se, if more water is applied than can drain away from the soil. The poor infrastructure is part of the problem. Leaky irrigation canals can also contribute to waterlogging. Furthermore, alkalinization can clog the soil pores, making it difficult for the water to drain. To remedy the problem, one has to stop the seepage from canals by means of proper lining and maintenance. Furthermore, one should put a drainage system in place. This is, however, very costly. It may cost five times more than the other infrastructure that has gone into the project.

Waterborne diseases

A problem related to waterlogging is that dams and their distribution canals may give rise to pools of stagnant water. These pools have a tendency to serve as breeding grounds for vectors of waterborne diseases. This is a major problem in many developing countries.

Diseases spread by water related vectors are malaria, yellow fever, and dengue fever. While these diseases are not directly attributable to water quality, they are often spread by large-scale development of water systems that create conditions favorable to their hosts.

Water-based diseases come from hosts that either live in water or require water for part of their life cycle. These diseases are passed to humans when they are ingested or come into contact with the skin. The two most widespread examples in this category are schistosomiasis, which result from contact with snails that serve as hosts, and dracunculiasis (guinea worm), which results from ingesting contaminated host zooplankton (Gleick, 1998).

Conclusion

Dams are not inherently good or bad. Many dams have been very helpful in the development of the human endeavor. However, in far too many cases, shortsightedness and tunnel visions have resulted in dams, where the economic return has failed badly to make up for the adverse environmental and social impact of the dam.

LARGE DAMS, STATISTICS AND CRITICAL REVIEW

Peder Hjorth, Lars Bengtsson
Department of Water Resources Engineering, Lund
University, Lund, Sweden

Definition

According to the International Commission on Large Dams (ICOLD), a large dam is one whose height is:

- 15 m or higher
 - Between 10 and 15 m if it meets at least one of the following conditions:
 - A crest length of not less than 500 m
 - A spillway discharge potential of at least 2,000 m³/s
 - A reservoir volume 15,000,000 m³ or more
- (Source: McCully, 1996)

Development of large dams and reservoirs

Precipitation is not evenly distributed over a region in either density or seasonality. For more than 5,000 years

water-retaining structures have been built in different parts of the world to ensure that water is available for domestic and agricultural purposes throughout the year (Biswas and Tortajada, 2001). Some 6,000 years ago, the Mioris reservoir, with an area of 2,000 km² and a volume of 12 km³, was constructed in the Nile Valley. Herodotus regarded it as one of the Seven Wonders of the World (Avakyan and Ovchinnikova, 1971).

According to the ICOLD “World Dam Register 1988,” (ICOLD, 1988) there were 427 dams in the year 1900 but not more than 10 of them were large. During the twentieth century, there was a tremendous upsurge in the construction of large dams. Dams were built to provide water for irrigated agriculture, domestic or industrial use, to generate hydropower, or to help control floods. In industrialized countries, the construction of large dams tended to take place mostly in the first half of the twentieth century while most large dams in developing countries tend to have been constructed after 1950. The ICOLD report tells that there were some 5,200 large dams in service in the world by 1950. Now 60 years later there are more than 45,000 large dams. Sixty percent of all rivers have dams. Thirty to forty percent of irrigated agriculture gets its water from dams and some 20% of global electricity comes from dams.

In 1945, the USA had the five largest dams in the world: Hoover Dam on the Colorado River, Bonneville Dam on the Columbia River, Fort Peck on the Missouri River, Shasta on the Sacramento River, and Grand Coulee on the Columbia River. Currently, the highest dams and largest reservoirs tend to be located in developing countries or in the former Soviet Union. A list of the highest dams is provided in Table 1. Table 2 is a list of the largest reservoirs.

As a dam construction, the Tarbela Dam on the Indus River in Pakistan is the largest in the world. The construction is 2,743 m wide with a maximum height of 143 m. The total volume of earth and rock used for the project is 152.8 million cubic meters.

The main purpose of building very large dams is hydropower production. Dams with the largest hydropower potential are listed in Table 3. The Itaipu Dam is the largest operating hydroelectric facility in terms of annual generating capacity, which is 90–95 TWh, while the annual generating capacity of the Three Gorges Dam has been about 80 TWh in the last few years.

For a long time, construction of large dams was seen, in many places, as a prerequisite for economic development and increased well-being. In India, e.g., nothing signifies this belief more than the temples at the sources of “sacred fliers” being substituted by dams – the “temples of modern India” as Nehru called them. Thus, large dams have traditionally been developed in accordance with the prevailing development paradigm, i.e., a firm belief in the merits of industrialization and domination of Nature. The benefits of large dams in the early stages were relatively easy to quantify. Hydropower, irrigation, and flood storage were approached as primarily a mass balance analysis related to timing and delivery of water. The downside

of these projects, when acknowledged, was approached from the perspective that any problem had an engineering “fix.” In hindsight, it is easy to critique this naïve approach of the original designs or approaches to resolve complex environmental issues.

From the 1930s to the 1970s, the construction of large dams became synonymous with development and economic progress. Viewed as symbols of modernization and humanity’s ability to harness nature, dam construction accelerated dramatically. This trend peaked in the 1970s, when on average two or three large dams were commissioned each day somewhere in the world. It was not until the late 1970s or 1980s that people started to appreciate the need for environmental and social impact assessments in the planning of large dam projects. By then, some 35,000 large dams had already been built. For many of these large dams the economic gains are dwarfed by the social and environmental costs. Past shortcomings and inequities remain unresolved, and experience with appeals, dispute resolution, and recourse mechanisms have been poor (World Commission on Dams, 2000). In industrialized countries, most of the criticism against large dams is related to the impacts on the aquatic ecosystem. In developing countries, however, social concerns tend to be more important. People have lost their land, their possibilities for flood-plain agriculture, or fishing opportunities due to dam constructions.

The most serious problem with large dams is the displacement of people. More than 45 million people have been displaced. The problem is worst in densely populated countries. It is estimated that some 35 million people have been displaced in India and some 10 million in China. Only the Three Gorges project has forced some 1.2 million people to move from their homes. In Scudder (2005) it is stated that living standard improvement occurred in only 3 cases out of 44 and were restored in only 5 cases.

Irrigation is a driving force behind the construction of many dams. In 1800, an estimated eight million hectares, an area about the size of Austria, were equipped with watering facilities. A number of large projects constructed during the nineteenth century, especially in India and what is now Pakistan, brought the total area irrigated to about 48 million hectares (Postel, 1993). As the world population has grown from 1.6 billion to 7 billion over a century, irrigation has become a cornerstone of global food security. The irrigated area nearly doubled in the first half of the nineteenth century. An even faster surge brought the total to more than 235 million hectares by the end of the century.

Irrigation projects generally endear themselves to agriculturalists because they tend to promote maximum yield per hectare. Also, irrigation projects have many attributes that satisfy the objectives of politicians, particularly a rapid, visible, and dramatic impact, and the tendency to be closely associated with a political promoter. Donors of foreign aid promote irrigation projects for similar reasons. However, lending for irrigation by the major international banks has declined after 1980, the main reason being that the costs of adding irrigation capacity – building new dams, reservoirs, canals, and distribution channels – have been rising in many countries, making it harder to justify such investments on economic grounds. Another reason is the poor performance and quality of many existing irrigation schemes. In many large surface water networks, less than half the water diverted from the reservoir actually benefits crops. Typical efficiencies for large projects in Asia run at about 30%. Much water seeps through unlined canals before it gets to the fields. An additional amount runs off the land or percolates

unused through the soil because farmers apply water unevenly, excessively, or at wrong times (Hjorth, 2001).

In Pakistan the World Bank has played a central role in the development of Pakistan's Indus Basin Irrigation System. Through the government's Revised Action Program (RAP) the emphasis shifted from development to improving system efficiency through rehabilitation and upgrading. An evaluation of the first four projects under the RAP strategy shows that although the water saved by these rehabilitation projects is little more than half of what was expected, this saved water is more than a new surface storage dam at Kalabagh would provide, and its unit cost is about one fifth of the expected unit cost of water from the Kalabagh Dam. The Kalabagh Dam Project was recently (2010) shelved because the four provinces of Pakistan were unable to reach an agreement on how the water from Kalabagh should be shared among them.

Dam failure

Dams may fail because of poor construction, poor management, or unexpected loads higher than those designed for. Some examples of dam break are given below.

In 1950, the Chinese Government announced the "Harness the Huai River" project. The dual purpose of the program was to (1) control the river and prevent flooding and (2) utilize the water captured for irrigation and hydro-power production. Under this program, two major dams were built, the Banqiao Dam on the Ru River and Shimantan Dam on the Hong River. The Ru and Hong Rivers are not tributaries of the Huai River but are part of the same river system as the Huai River, i.e., the Huang He (Yellow River) system. There were numerous smaller dams built as well. The Banqiao Dam was designed to protect from a 1,000-year flood, which was estimated to be a 3-day storm of 530 mm. The Shimantan Dam was to protect from a 500-year flood, which was estimated to correspond to 480 mm of rain over a 3-day period. In the beginning of August 1975, there was a set of storms giving well over 1,000 mm as areal rainfall over 3 days. Point rainfall in an individual gauge was measured to 1,650 mm in the 3 days. The Banqiao and Shimantan Dam reservoirs were filled above capacity because the inflow by far exceeded the capacity of the outlet sluice gates. On August 8, the Shimantan Dam collapsed. The dam failure created a 6 m high and 12 km wide wall of water. Altogether, 62 dams collapsed and the flood spread over more than a million hectare of farmland throughout 29 counties and municipalities. At least 50,000 died and 11 million people in the region were affected. The observed precipitation and the observed-computed river flow in the Hong River are shown in Figure 1 (drawn from data from Bengtsson et al. (1995)). There were no river flow measurements after the collapse of the dams. Comparison with all previous and later river discharge is seen in Figure 2.

Another example is the Vaiont Dam in Italy. It is one of the tallest dams in the world; it is 262 m high, 27 m thick at the base, and 3.4 m at the top. It was overtopped in 1963. Warning signs of geological instability during the early stage of filling were disregarded, and the attempt to

Large Dams, Statistics and Critical Review,

Large Dams, Statistics and Critical Review, Figure 2 River discharge Hong River, China. The observed flow was 400 m³/s prior to the collapse. The observations could not be continued but from hydrological modeling the peak after the dam break was estimated to 550 m³/s.

complete the filling led to a landslide, which created a gravity wave that brought massive flooding and destruction to the downstream Piave Valley, where several villages were wiped out. Some 2,000 people were killed. The dam structure was not damaged, but the dam reservoir has been kept empty since the accident.

The Teton Dam on the Teton River Canyon in Idaho, USA, failed during filling on June 5, 1976. The failure created a flood wave that killed 11 people and 17,000 head of cattle. Total damage estimates have ranged up to US \$2 billion. The dam was never rebuilt (Mark, 1993).

Review from the World Commission of Dams (WCD)

The Commission's two objectives with the review were:

- To investigate the effectiveness of large dams and assess alternatives for water resources and energy development
- To develop internationally acceptable criteria, guidelines, and standards for the planning, design, appraisal, construction, operation, monitoring and decommissioning of dams

Key recommendations in the WCD final report include the following:

- No dam should be built without the “demonstrable acceptance” of affected people, and without the free, prior, and informed consent of affected indigenous and tribal peoples.
- Comprehensive and participatory assessments of people’s water and energy needs, and different options for meeting these needs, should be developed before proceeding with any project.
- Priority should be given to maximizing the efficiency of existing water and energy systems before building any new projects.
- Periodic participatory reviews should be done for existing dams to assess such issues as dam safety, and possible decommissioning.
- Mechanisms should be developed to provide reparations, or retroactive compensation, for those who are suffering from existing dams, and to restore damaged ecosystems.

In assessing the large dams reviewed by the Commission it was found that:

- Large dams display a high degree of variability in delivering predicted water and electricity services – and related social benefits – with a considerable portion falling short of physical and economic targets, while others continue generating benefits after 30–40 years. Large dams have demonstrated a marked tendency toward schedule delays and significant cost overruns.
- Large dams designed to deliver irrigation services have typically fallen short of physical targets, did not recover their costs, and have been less profitable in economic terms than expected. Large hydropower dams tend to perform closer to, but still below, targets for power generation, and generally meet their financial targets but demonstrate variable economic performance relative to targets, with a number of notable under- and over-performers.
- Large dams generally have a range of extensive impacts on rivers, watersheds, and aquatic ecosystems, and in many cases have led to irreversible loss of species and ecosystems.

Historically, social and environmental impacts were left outside the assessment framework and the role of impact assessments in project selection remained marginal, even into the 1990s. Conflicts over dams have heightened.

Summary

The debate about dams is a debate about the very meaning, purpose, and pathways for achieving development. This suggests that decision-making on water and energy management should align itself with the emerging global commitment to sustainable human development and on the equitable distribution of costs and benefits. When the 45,000 large dams of today were assessed and

commissioned, environmental and social aspects were often neglected. Thus, there is a need to reassess old dams. The challenge is to more accurately define the economic, social, and environmental parameters in a basin context and develop a portfolio of appropriate response mechanisms. There is a need for genuine democracy including public participation and transparency in the development and implementation of energy and water policies.

Dams are neither inherently good nor inherently bad. They have been used to support the development models that prevailed at different times. An international overview of trends within the water sector shows that there is a remarkable communality in trends and patterns, i.e., intersectorial and interregional water allocation conflicts, concerning poor cost recovery and poor operational performance, and excessive government involvement and bureaucratic control. The use of water power and the development of irrigation schemes, both of which have a long, and most often, highly successful history, have to be approached anew. A subtle approach is needed, one that does not result in displaced populations, but one that does care for people, the environment, and marine food-chains.

Introduction

The Laurentian Great Lakes represent an extensive, interconnected aquatic system dominated by its coastal nature. While the lakes are large enough to be significantly influenced by the earth's rotation, they are at the same time closed basins to be strongly influenced by coastal processes (Csanady, 1984). Nowhere is an understanding of how physical, geological, chemical, and biological processes interact in a coastal system more important to a body of water than the Great Lakes. Several factors combine to create complex hydrodynamics in coastal systems, and the associated physical transport and dispersal processes of the resulting coastal flow field are equally complex. Physical transport processes are often the dominant factor in mediating geochemical and biological processes in the coastal environment. Thus, it is critically important to have a thorough understanding of the coastal physical processes responsible for the distribution of chemical and biological species in this zone. However, the coastal regions are not isolated but are coupled with mid-lake waters by exchanges involving transport of materials, momentum, and energy.

This review will focus on several mechanisms that contribute to the alongshore and cross-shore transport of material. These are (1) wave-driven processes, (2) coastal boundary layer processes including upwelling and downwelling flows, (3) episodic events such as storms, (4) the thermal bar, and (5) river plumes.

Subregions of the coastal zone

The first characteristic feature of coastal waters is their shallow depth, typically 0–20 m, compared with lake-average depths of 60–150 m except Lake Erie. The near-shore or coastal zone in the Great Lakes is defined as the zone that begins at the shoreline or the lakeward edge of coastal wetlands and extends offshore to the depth where the thermocline typically intersects with the lake bed in late summer or early fall (Rao and Schwab, 2007). This

delineation also includes the surf and swash zones in the littoral zone. Because of shallow depths in the coastal zone, currents near the bottom are often much larger than in deeper areas. Bottom friction plays a significant role in nearshore dynamics. The presence of the shoreline acts as a lateral constraint on water movements, tending to divert currents so that they flow nearly parallel to the shoreline. The shoreline also causes surface slopes to develop, which in turn affect water movements. The influx of freshwater runoff from the land affects the density of the coastal water. For a similar heat flux through the sea surface, the shallower water near the coast undergoes larger changes in temperature than deeper water. Because of these effects, coastal waters of the Great Lakes exhibit large horizontal gradients of density, often associated with changes in currents. The Great Lakes also undergo a complete cycle of isothermal to vertically stratified conditions in a year. The thermal structure in the Great Lakes generally depends on the season because of the large annual variation of surface heat fluxes (Boyce et al., 1989). During the unstratified period, storm action is the most important forcing, as higher wind speeds and the absence of stratification allow the wind forcing to penetrate deeper into the water column. In summer and fall most of the lakes are stratified with a distinct thermocline in the upper 20–30 m (Boyce et al., 1989).

Horizontal spatial scales of coastal physical processes can range from 10 m in nearshore areas for surface gravity waves to hundreds of kilometers for large-scale wind-driven flows. The flow regimes of the coastal zone are not all uniform from nearshore to offshore waters but vary appreciably as water depth changes. For convenience, the coastal zone can be divided into three regimes, namely, (1) the nearshore area consisting of swash and surf zones, (2) the frictional and inertial boundary layers, together known as coastal boundary layer (CBL), and (3) the open lake (Figure 1). In the open lake the momentum imparted by the wind stress is balanced by the Coriolis force, frictional forces are small, and wave-induced bottom agitation is minimal. In contrast, the frictional boundary layer (FBL) is dominated by bottom friction and lateral friction. At around 3 km from shore an outer boundary layer, known as the inertial boundary layer (IBL) develops due to the adjustment of inertial oscillations to shore-parallel flow (Rao and Murthy, 2001). Wave run-up and breaking waves are dominant sources of mean flows within the swash and surf zones.

Wave-driven processes

The wind excites surface waves that create hazardous conditions for recreation and navigation and are also the main cause for shoreline erosion. The most common wind directions over the Great Lakes region are south-westerly to westerly, but in a climate which is extremely variable from day to day, winds from other directions are quite

Laurentian Great Lakes, Interaction of Coastal and Offshore Waters, Figure 1 Schematic diagram of the subregions of the coastal zone (Source: Rao and Schwab, 2007).

frequent, and strong spells of easterly or north-easterly winds are not unusual. As wind-generated waves propagate from deeper water toward the shore, wave orbital motions must adjust to the shallower water depths, modifying the wave kinematics. Therefore, the greatest effect of wind waves occurs in the surf and swash zones. Inputs of storm runoff, combined sewer overflows, and streams occur in this zone. The swash zone with wave run-up and run-down on a beach forms the boundary between the surf zone and the backshore. It also determines the landward boundary of the area affected by the wave action. The surf zone is the area of water between the swash zone and the seaward side of breaking waves. The width of the surf zone is very small compared to the total width of the coastal boundary layer. In contrast to other regimes in the coastal zone, the surf zone is severely constrained laterally; therefore the geostrophic effects (steady currents sustained by a balance between the pressure gradient force and the Coriolis force) are negligible. Circulation is driven almost exclusively by forces resulting from the dissipation of breaking waves. The net onshore transport of water by wave action in the breaker zone, the lateral transport inside the breaker zone by longshore currents, and the seaward return of the flow through the surf zone by rip currents constitute a nearshore circulation system. Wave-generated currents, which transport beach material, are an important factor in the beach stability. The direction of littoral drift is determined by the angle of wave approach and associated longshore currents, and is particularly critical during periods of high lake levels. The predominant direction of the littoral drift depends on non-storm waves that contain much more total energy than is contained in storm waves of shorter duration. Wave-generated currents carry some

particles along the bottom as bed load, while other particles are carried some height above the bottom as suspended load.

The coastal boundary layer

The coastal boundary layer is the region between the wave-breaking zone and the open lake where frictional forces and the steering affect of the shore are dominant processes. The prime driving force of circulation in this zone is again the wind; however, the effects of stratification can become very important during the summer period. The wind action on coastal waters rapidly generates flow predominantly parallel to the coast. When a steady wind blows across a lake, the equilibrium condition of the water surface is a depression along the upwind end and an increase of elevation (storm surge) along the downwind end of the lake. Surface seiche, which is the oscillatory response of the lake surface after wind cessation, can also have a significant impact on the nearshore circulation in some of the Great Lakes. When a steady wind over the homogeneous lake pushes water downwind, the water level rises, and the resultant pressure gradient causes a return flow in the deeper parts of the lake forming two counter-rotating gyres.

Winds at mid-latitudes are usually quite variable, rarely displaying significant persistence for more than a day. Under these circumstances the transient properties of coastal currents are often of greater practical importance than the steady state for constant wind. These transient properties depend on the frequency of weather cycles. A particularly notable feature of coastal currents in the Great Lakes is the presence of inertial oscillations during the stratified period. At the latitude of the Great Lakes the inertial period is close to 17 h. Although these

oscillations are more like an organized flow, because of their oscillatory nature they can be viewed as large-scale fluctuations and as such contribute to dispersal processes in the coastal zone. In the coastal zone, these types of rotary motions are modified since the particle velocities perpendicular to the coast must vanish at the shoreline. Consequently, there is an adjustment zone, typically 5–10 km wide often referred to as the coastal boundary layer (Figure 2).

During the stratified season significant wind events cause upwelling and downwelling of the thermocline along the shore and within the CBL. If the coast is to the left of the prevailing winds, the wind-induced Ekman transport will be away from the coast in the surface layer and upwelling occurs near the coast. During this period an onshore and upslope transport occurs at some depth below the surface. On the other hand, if the coast is to the right of the wind, downwelling occurs. The transport in the surface layer is toward the coast, and offshore transport occurs below the surface layer. The changeovers from upwelling to downwelling regimes and vice versa are of particular interest to nearshore biology and chemistry studies. The offshore distance scale over which these events take place depends on the wind stress and near-shore bathymetry (Csanady, 1984) and is known as the Rossby radius of deformation (typically of the order of 3–5 km). In this zone a balance exists between wind stress, Coriolis force, and internal pressure gradient. A typical changeover from upwelling to downwelling is accompanied by marked changes in the thermal structure in this zone in a period of 4–5 days, exposing the zone to either epilimnetic water or hypolimnetic water depending upon the situation. Upwelling and downwelling have the

potential to produce large onshore-offshore transport of material.

During the stratified season in the Great Lakes two types of internal waves often occur after a strong wind event: Poincaré waves and internal Kelvin waves. Poincaré waves are the near-inertial period basin-wide oscillations of the thermocline characterized by anticyclonic phase propagation. These waves were first observed in the Great Lakes by analyzing temperature observations at municipal water intakes for cities around Lake Michigan (Mortimer, 1963). On the other hand, internal Kelvin waves are coastally trapped oscillations of the thermocline that progress cyclonically around the lake with a phase speed of 0.5 m/s (Beletsky et al., 1997). During periods of calm or weak meteorological conditions, coastal currents are usually weak. Experiments conducted on the Great Lakes showed that significant mass exchange between the CBL and offshore waters takes place during episodic events and the current reversals associated with the propagation of internal Kelvin waves. Complex patterns of cross-shore transport have been observed in upwelling systems including the Great Lakes.

Episodic events in Great Lakes

Circulation in the Great Lakes is also highly episodic with the most energetic currents and waves occurring during the strongest storms. During fall and winter seasons, the higher wind speeds and the absence of the thermocline allow the effects of wind action to penetrate deeper into the water column. In the Great Lakes, the gradients of many biogeochemically important materials are considerably higher in the offshore direction than in the alongshore direction. In the presence of these large gradients,

Laurentian Great Lakes, Interaction of Coastal and Offshore Waters, Figure 2 Mean alongshore and cross-shore components of currents (Source: Rao and Murthy, 2001).

cross-isobath circulation is a primary mechanism for the exchange of material between nearshore and offshore waters. Spring and fall storms can create a nearshore zone of turbid water up to 10 km wide which sometimes encompasses a significant portion of the lake's coastal zone (Figure 3). Much of the resuspended material consists of fine-grained silty clay that can remain in suspension for several weeks after a storm. The total estimated amount of material resuspended during a large event can be comparable to the total annual load (erosion, atmospheric deposition, and tributary input) of fine-grained material to the entire basin.

In the case represented in Figure 3, it was observed that in the shallow waters of the southern basin of Lake Michigan, the water near the coasts moves in the direction of the wind toward the south, while return flow occurs in the deeper parts of the lake. This process forms two counter-rotating closed gyres, a cyclonic gyre to the right of the wind and an anticyclonic gyre to the left. These gyres are one of the important mechanisms for nearshore-offshore transport in the Great Lakes since they generate an area of intense offshore flow where they converge at the downward end of the lake. The mean and fluctuating coastal currents in southeastern Lake Michigan were studied during the winter and early spring during the three field years of the Episodic Events Great Lakes Experiment (EEGLE). The winter-spring currents in this region are quite depth-

independent, and the vortex mode identified earlier in offshore waters is also evident in the data from these coastal waters. The net seasonal currents during the winter season flow predominantly alongshore and toward the north. Time varying alongshore circulation is more closely tied to the alongshore component of the wind. The net offshore transport appears to be a result of the combination of wind-forced two-gyre circulation, Ekman veering of bottom boundary layer currents, and the topographic steering. However, the interannual variability of current speeds and magnitudes seems to be caused mainly by variability of surface wind forcing. The intermittent episodic circulation influenced by northerly storms causes significant asymmetry in the mean circulation pattern. There is also significant variability of circulation from one storm to another. The alongshore currents were initially driven by strong northerly wind pulses, but subsequently reverse direction as the forcing stops. The two-gyre circulation seems to be an important mechanism for the relaxation of currents as well as the offshore transport in the southern Lake Michigan. Direct wind-forced offshore transport was also observed in some regions.

The thermal bar

The thermal bar is a downwelling plume of freshwater at the temperature of maximum density (4°C), and is formed in temperate lakes in spring and fall when waters on either

Laurentian Great Lakes, Interaction of Coastal and Offshore Waters, Figure 3 Satellite picture showing reflectance during a winter storm in Lake Michigan.

side of the 4°C isotherm mix (Figure 4). The density-induced horizontal circulation in large temperate lakes of the northern hemisphere is counter-clockwise in the stably stratified nearshore region, and clockwise in the deep water region. The secondary circulation, perpendicular to the primary one, consists of two circulation cells, one on each side of the 4°C isotherm, where coastal and offshore waters mix and descend. This two-cell thermal bar circulation is important because of its role in inhibiting the horizontal exchange of water between the nearshore and offshore regions. The thermal bar can significantly affect the flow and thermal characteristics of the Great Lakes and may have significant influence on their ecological functioning. This effect is extremely important because a proper understanding of an ecosystem's interaction with the hydrodynamics is required to determine optimum nutrient loadings to the lake.

In the 2003 Lake Ontario experiment, the coastal circulation was mainly influenced by the alongshore winds.

One of the interesting observations in this experiment is that the thermal bar was stationary for several days. Although mean cross-shore flow decreased during the thermal bar period, the flow was depth-dependent. In general, theoretical models overestimated the progression rate of the thermal bar during the early phase. In the later phase, the models that incorporated the effect of horizontal heat flux in the thermal bar region were able to predict the significant increase in the progression rate. This study concluded that the effect of wind on the thermal bar seems to be an important feature and the models have to incorporate this effect. Also, the horizontal turbulent exchange parameters showed non-isotropic conditions in the shallow stably stratified region. The alongshore horizontal exchange coefficients were higher than cross-shore exchange coefficients. During the thermal bar period, the magnitude of both alongshore and cross-shore exchange coefficients decreased when the bar was in the nearshore zone and from mid-depth onward the thermal bar has not

Laurentian Great Lakes, Interaction of Coastal and Offshore Waters, Figure 4 Schematic diagram of the spring thermal bar (From Henderson-Sellers, 1984).

Water-quality analyses of the Niagara River have shown high concentrations of toxic chemicals that are introduced by the river plume into Lake Ontario. Much research has been conducted to investigate the dynamics of the Niagara River inflow into Lake Ontario. The near-shore thermal structure is altered significantly by the inflow, the warmer Niagara River plume extends beyond the river mouth in excess of 10 km, after which it eventually mixes with the ambient lake water. The vertical extent of the Niagara River plume can be 8–10 m, with the warmer inflowing water developing a frontal structure as it enters the lake. The gradient across the thermal front depends on the time of year and therefore on the difference between the temperature of the inflowing water and the ambient lake temperatures.

Prevailing wind conditions and lake circulation patterns determine the spread of the Niagara River plume in Lake Ontario. In most circumstances, a plume develops from the Niagara River mouth and tends to extend eastward along the south shore of the lake. In the initial phase, horizontal velocities from the Niagara River mouth are reduced significantly, and the river water is vertically well mixed over the shallow bar area. Beyond this initial phase, the river plume is deflected in response to lakewide circulation and the prevailing winds. In the transition phase, a large clockwise eddy between 10 and 12 km in diameter is formed to the east of the Niagara River mouth. The eddy appears often and lasts for a few days. From a water-quality standpoint, river outflow that is entrained into this zone of low net transport is effectively isolated from the mixing effects of the main shore-parallel currents. Consequently, this nearshore area can be a zone in which fine particulate material is deposited (Figure 5).

Introduction

Photosynthesis is the primary source of energy that supports all aquatic life in the oceans, lakes, and reservoirs. It is of fundamental importance since it sets overall constraints on the flow of material and energy in aquatic ecosystems. Phytoplankton, through the process of photosynthesis, fix atmospheric carbon and become the base of the aquatic food web. Rates of photosynthesis are dependent on the intensity and spectral quality of light, which in the aquatic environment are in turn related to the optical characteristics of the water and depth, and the rate at which the phytoplankton circulate through the water column. This entry provides a brief overview of the factors influencing the underwater light climate and photosynthetic primary production, as well as some of the most common methodologies that have been widely employed to quantify rates of aquatic photosynthesis.

It is also important to acknowledge that over the last several decades it has become clear that in water bodies, which receive significant loads of dissolved organic carbon (DOC), the primary source of energy to the aquatic food web is this DOC being metabolized by aquatic bacteria. This “microbial loop” (Tranvik, 1992) is common in lakes with forested watersheds such as those found across the boreal region, where the DOC inputs supporting the aquatic food web may in fact be largely the result of terrestrial photosynthesis in the forested watersheds surrounding the lakes (Figure 1). In other cases, such as clear water lakes or the oceans, inputs of DOC are of lesser importance, and aquatic food webs will be supported to a much greater extent by phytoplankton photosynthesis.

The basic chemical equation describing photosynthesis (Equation 1) describes the process by which carbon dioxide and water are transformed by photosynthesis into carbohydrates (also referred to as sugars or photosynthate).

Light and Primary Production in Lakes, Figure 1 Simplified diagram showing the relative roles of primary production and microbial processes in supporting the aquatic food chain. The importance of the microbial loop is greatly enhanced by external loading of DOC.

Measurement of aquatic photosynthesis is based on either quantifying the removal of carbon dioxide (CO_2) from the water, or the evolution of oxygen from the photosynthesizing phytoplankton. Oxygen evolution by the phytoplankton is balanced by respiration (R), which using the stored photosynthate, removes dissolved oxygen (DO) from the water and releases CO_2 back into the water.

Measurements of primary production can account for both photosynthesis and respiration. Gross primary production (GPP) is the total carbon uptake by the phytoplankton, whereas Net Primary Production (NPP) is $\text{GPP} - \text{R}$ or the difference between carbon uptake due to photosynthesis and carbon loss due to respiration. When using these terms the context of scale is of importance. Measurements made on a incubated sample over a short time interval will tend to represent processes occurring in an isolated part of the water body from which the sample was obtained. For example, an incubation that measures the uptake of carbon over relatively short time-scales where R does not significantly reduce the recently acquired carbon are often considered GPP. Net Ecosystem Production (NEP), although calculated in the same way

($\text{GPP} - \text{R}$), differs from NPP in that NEP accounts for GPP and R in the entire aquatic ecosystem. While in theory estimates of GPP and R made from isolated samples could be scaled up to give ecosystem values, NEP is usually based on measurement methodologies that attempt to account for system-wide changes in CO_2 or O_2 .

Underwater light

Primary production is of course a function of light or more precisely the photon flux density that can be absorbed by the phytoplankton photosynthetic pigments. It is therefore, both the intensity and spectral composition of the light that influences the rate of photosynthesis. In practice, when estimating primary production, the preferred measure of light is photosynthetically active radiation (PAR).

$$\text{PAR} = \int_{700}^{400} E_d(\lambda) d\lambda \quad (2)$$

where PAR is the integral photon flux between 400 and 700 nm measured as $\mu\text{moles m}^{-2} \text{s}^{-1}$ (also referred to as $\mu\text{E m}^{-2} \text{s}^{-1}$), and E_d is downwelling photon irradiance at wavelength (λ).

PAR is attenuated with depth as a consequence of both absorption and scattering of photons as they pass through the water, and this rate of attenuation can be described by Equation 3

$$E_d = E_0 e^{-K_d \cdot z} \quad (3)$$

where E_d is the downwelling irradiance at depth z and E_0 the downwelling irradiance just below the surface (depth 0). E_d can be either wavelength specific or integrated over the PAR wavelengths. K_d is the diffuse attenuation coefficient of downwelling irradiance, which can in turn be calculated from a profile of underwater irradiance measurements. Commercial instruments are available that measure underwater light both spectrally, or more commonly as a single irradiance over the PAR bandwidth. K_d (m^{-1}) is equal to the slope of the relationship of the natural log of irradiance versus depth. K_d can be related to the coefficients of absorption scattering using an approximate relationship (Kirk, 1981)

$$K_d(\lambda) = \sqrt{a(\lambda)^2 + 0.256a(\lambda)b(\lambda)} \quad (4)$$

where a and b are the coefficients of absorption and scattering (m^{-1}). Similar relationships which explicitly account for the variation in solar angle and the three-dimensional scattering characteristics of the water (volume scattering function) are also available (Kirk, 1994).

As can be seen from Equation 4, in all but the most turbid waters, the greatest effect on attenuation occurs through absorption. Scattering in the upward direction (backscattering) will directly affect attenuation, while forward scattering will also increase attenuation by increasing the path length that a photon takes to reach a depth and therefore the probability of absorption. It is because of the effects of scattering that K_d is most correctly referred to as the *diffuse* attenuation coefficient.

The attenuation coefficients of different waters, and therefore the light available to support photosynthesis in different waters will be dependent on the concentrations of absorbing compounds or optically active substances in the water, namely, the concentrations of phytoplankton, colored dissolved organic matter (CDOM), and detrital particulate matter, as well as the absorption of pure water itself (Figure 2).

It is the concentration and interaction of these absorbing compounds that influence the attenuation of PAR and the spectral quality of PAR in different water bodies. From Figure 3, which shows the spectral composition of irradiance in the Swedish great lakes, the importance of variations in the concentrations of optically active substances, particularly CDOM (Figure 2b), becomes apparent. Increasing CDOM absorption in the blue to green wavelengths (400–550 nm) greatly influences the magnitude and spectral shape of the subsurface irradiance spectra. Not only is PAR attenuated more rapidly in the more

colored waters, a much greater proportion of PAR occurs in the longer wavelengths in these waters. This results in the light affecting photosynthesis mostly occurring in the red phytoplankton absorption peak (~660–670 nm, Figure 2c) in the more colored waters, while in clearer Lake Vättern the broader blue (~400–500 nm) phytoplankton absorption is also of importance in influencing photosynthesis.

A more precise definition of light in relation to photosynthesis was defined by (Morel, 1978) that accounts for spectral variations in irradiance and phytoplankton absorption. Photosynthetically useable radiation (PUR) is calculated as the integral of the product of the underwater light spectra and the spectral phytoplankton absorption coefficient. While this, as the name suggests, provides a much more accurate estimate of the available light that could drive photosynthesis, it is not as widely used as PAR due the added requirement to measure spectral irradiance and phytoplankton absorption.

Measurement of primary production

Some of the first estimates of aquatic primary production were made using chemical estimates of changes in DO concentration (Odum, 1956). Increases in DO concentration when phytoplankton are exposed to light are a measure of NPP under illuminated conditions, whereas depletion of DO in the dark is a measure of R. Both illuminated and dark measurements are often combined to calculate GPP, R, and NPP. The advantage of this method is that it is simple to use and based on a relatively common chemical water quality test that is well described and easily used. The disadvantage is that the precision of the method was not so high as to allow for rapid assessments or measurement in low productivity systems.

In the 1950s, use of the radioisotope ^{14}C was introduced as a means of sensitively estimating the uptake of carbon by phytoplankton (Steemann-Nielsen, 1952; Rodhe, 1958). When added to water as bicarbonate ($H^{14}CO_3$) the radiolabeled carbon equilibrates with dissolved CO_2 and is taken up by photosynthesis and incorporated into cellular carbohydrates. If the phytoplankton are then collected, the incorporated ^{14}C can be sensitively estimated by liquid scintillation counting, and from knowledge of the ratio of ^{14}C to total dissolved inorganic carbon in the incubated sample, total carbon uptake can be estimated. The advantages of this method is that it is much more sensitive than DO methods allowing accurate measurements in low productivity water bodies, as well as short-term measurements which reduce the containment affects associated with incubation. The disadvantage of the ^{14}C method is that it does involve radioactive substances which require a greater level of care and skill in handling. Unlike the oxygen, method ^{14}C estimates of productivity do not give estimates of R, but instead give an approximate estimate of GPP.

When photosynthesis is estimated by measuring the rate of carbon uptake or DO evolution three basic measurement strategies are generally used: (1) incubation of samples in the lake at the in situ conditions from where

Light and Primary Production in Lakes, Figure 2 Spectral variations in the absorption of water from Sweden's three largest lakes: Mälaren, Vänern, and Vättern. (a) Variation in total absorption spectra between lakes. (b) Variation in CDOM absorption between lakes and the absorption spectra of pure water. It is the combined effects of water and CDOM that most strongly affect the total absorption characteristics of the lakes. (c) Variations in phytoplankton absorption between lakes. These spectra were simulated using the methods described by Pierson and Strömbeck (2000) based on the median concentrations of optically active substances (d) that can be estimated from long-term monitoring data.

Light and Primary Production in Lakes, Figure 3 (a) Spectral variations in subsurface irradiance in lakes Mälaren, Vänern, and Vättern. All measurements were made at the 3 m depth at midday under clear sky conditions. (b) Differences in the spectral shape of the subsurface irradiance are enhanced by normalizing the irradiance at each wavelength by the integral PAR irradiance associated with that spectra.

the samples were obtained, (2) short-term incubation in the laboratory, and (3) monitoring of diel variations in free water DO using electrochemical sensors.

In situ incubation

Measurements of primary production can be estimated from the changes in the concentrations of either DO or ^{14}C in samples incubated over a given time interval. One way to accomplish this is to incubate the samples under the same conditions from where they were collected. This is commonly referred to as in situ incubation. Water is collected from a number of depths within the euphotic zone (between the surface and the depth of 1% PAR attenuation), the initial concentration at each depth is measured, the samples are placed in clear (light) and dark (0 light transmission) bottles and resuspended at the depth and ambient conditions from which the samples were obtained. After a given time (often 4 h) the bottles are retrieved, the sample fixed to stop further biological activity, and the concentrations measured. When measuring oxygen, increases in light bottle DO can be used as an estimate of NPP over the time of incubation, whereas reductions of DO in the dark bottles give an estimation of R. GPP can be calculated as the sum of NPP from the light bottle and R from the dark bottle. When measuring ^{14}C uptake, increases in algal ^{14}C over the time of the incubation is an approximate measurement of GPP

since it is assumed that equilibrium between the cellular concentrations of labeled and non-labeled carbohydrates is not complete, and that the alga respiration of ^{14}C is not in proportion to the true rate of respiration. Dark bottle changes in ^{14}C are therefore small and only used as a background correction.

Some measurement of algal biomass (often chlorophyll) is usually made at each depth so that the production rates can be normalized to biomass. Measurements at the different depths can be integrated vertically to give areal rates of production (Figure 4).

The disadvantage to in situ incubation is that the phytoplankton may not in fact be exposed to the true conditions that they would actually experience in the lake, if the water is circulating within the euphotic zone. The phytoplankton may adapt to the light conditions in the incubation bottles (photoadaptation), and these light levels may differ in both intensity and spectral quality from the light that would on average be experienced by phytoplankton freely circulating through the water column. As a result of such differences in light exposure the production estimated from the incubation can be different from true in situ levels. A related problem is that samples exposed at shallow depths may receive artificially high levels of light exposure sufficient to reduce levels of photosynthesis as a result of photoinhibition, and this will again lead to errors in estimating true levels of production.

Light and Primary Production in Lakes, Figure 4 Primary production measured using ^{14}C incubation method Lake Erken, Sweden (Pierson Unpublished). (a) Vertical profile of estimated rates of carbon uptake line is mean of two replicate measurements at each depth. Lower productivity in surface bottles is likely due to containment effects. (b) Surface PAR irradiance on day of experiment. Shaded section corresponds to the time of the experiment.

Modeling: use of the PI relationship

Data obtained from in situ incubations can be integrated over the depths of measurements to give an estimate of water column productivity over the course of the incubation (Figure 4). However, to estimate productivity over longer timescales, simply extrapolating through time between separate in situ estimates of productivity will be subject to error as a result of variations in light intensity over diurnal to seasonal timescales, and to a lesser extent changes in water transparency (K_d Equation 3). A better method to estimate daily-seasonal variations in primary productivity is to use the incubation to measure the relationship between light intensity and primary production and to parameterize these data into an equation that predicts primary production as a function of light intensity. The relationship between light intensity and primary production is commonly referred to the photosynthesis–light or production–irradiance (PI) relationship. Common equations describing the PI relationship are given by Jassby and Platt (1976) and they recommend Equation 5

$$P^B(I) = P_{\max}^B \tan h\left(\alpha^B \frac{I}{P_{\max}^B}\right) + R^B \quad (5)$$

where $P^B(I)$ is photosynthetic rate normalized to phytoplankton biomass (chlorophyll) ($\text{mgC mgChl}^{-1} \text{h}^{-1}$) at a given PAR irradiance ($\mu\text{mole m}^{-2} \text{s}^{-1}$), $P_{\max}^B$ is the light saturated maximum level of photosynthesis ($\text{mgC mgChl}^{-1} \text{h}^{-1}$), α^B is the slope of the initial light limited portion of the PI curve ($\text{mgC mgChl}^{-1} \text{h}^{-1} [\mu\text{mole m}^{-2} \text{s}^{-1}]^{-1}$), and R is any increase in carbon due to respiration ($\text{mgC mgChl}^{-1} \text{h}^{-1}$).

Seasonal estimates of primary production can then be estimated from measurements of surface PAR irradiance which when input to Equation 3 can be used to predict the temporal variations in light with depth. Combining the predicted light with the PI relationship (Equation 5) allows estimates of primary production to be integrated both over depth and through time. Modeled variations in primary productions therefore depend on measured variations in surface PAR irradiance, and an assumption that phytoplankton biomass, K_d and the PI parameters $P_{\max}^B$ and α^B remain relatively constant. While in reality none of these are constant, they are not as temporally variable as surface irradiance, and assuming constant values allows estimations of areal primary production that do account for short-term variations in light intensity (Pierson, 1989). Errors can be reduced by regular sampling to account for variability in the fixed parameters.

While in theory it is possible to estimate the PI relationship from in situ incubations, this is difficult since sky conditions are rarely cloud-free during the entire incubation (Figure 4b), and therefore, the full range of light intensity that could be experienced by the phytoplankton over longer time intervals are rarely measured during the incubation period. There are also a limited number of light levels that can be measured by the in situ technique due to sample processing time and practical limitations on

the number of samples that can be suspended throughout the euphotic zone. Lewis and Smith (1983) introduced a rapid ^{14}C incubation method that overcame many of these problems. The “photosynthetron” incubator was deployed either in the laboratory or on ship, and consisted of manifold that held 25–50 scintillation vials over a strong light source. Between the light and the individual vials were differing levels of neutral density filters, so that the PAR exposure in the vials covered the full range that could be expected in the natural environment (approximately, $0\text{--}2,000 \mu\text{moles m}^{-2}\text{s}^{-1}$). A water sample was strongly enriched with ^{14}C and rapidly dispensed into all vials. The vials were cooled to in situ water temperature, and were illuminated for 20–30 min. At the end of the incubation, the samples are fixed to prevent further photosynthesis, and the excess inorganic ^{14}C in the sample is removed by acidification, before the organically bound ^{14}C was measured by liquid scintillation counting.

The advantages of this method are that photosynthesis is measured over a large range of light intensity, ensuring the PI relationship is well represented (Figure 5), and that confident estimates of α and $P_{\max}$ can be made for further modeling of lake system productivity. The short incubation time also minimizes adaption of the phytoplankton to the incubation light intensity so that the PI relationship obtained should be more reflective of phytoplankton light adaptation to true in situ light levels. Consequently, this method also provides a means to monitor changes in the PI relationship over time and space.

The main disadvantage of this method is that the incubation should be done on ship or at laboratory close to the water body, so that the phytoplankton do not acclimatize to the low light in the sample bottle. The second disadvantage is that the spectral quality of the PAR in an incubator illuminated by an artificial light source will not be the same as the spectral quality in situ. This can lead to some error in the estimates of the true in situ PI relationship.

Free water monitoring

A final means of estimating lake primary production and metabolism is by monitoring the free water concentration of DO using oxygen sensors suspended in the lake mixed layer. In situ changes in DO are estimates of NEP since they include the net effect of photosynthesis and respiration in the water volume measured. Furthermore, night time changes in DO can be assumed to be a result of R alone. This method has become more practical with the advent of optically based oxygen sensors that show lower levels of drift and require less frequent calibration, and the availability of low cost and reliable data loggers that allow reliable recording of high-frequency data. Often the sensor and data logger are combined into a single sonde system that can be moored unattended at depth, and retrieved periodically for data collection and sensor calibration.

Free water methods for estimating GPP, R , and NEP are reviewed by (Staehr et al., 2010). From frequent measurements (hourly or less) of DO, estimates of NEP are

Light and Primary Production in Lakes, Figure 5 An example of the relationship between biomass-specific photosynthesis and PAR irradiance measured in a laboratory incubator using ^{14}C . Photosynthesis initially increases linearly with irradiance at a slope of α^B . At an irradiance of IK photosynthesis reaches the light-saturated rate of $P_{\max}^B$. At even higher irradiances a decline in photosynthesis with a slope of β may occur due to photoinhibition (from Pierson, 1989, 1990).

calculated. Interval estimates of NEP can be extrapolated over the day (light period), and overnight to get estimates of R . If the assumption is made that the rate of R derived from night time measurements is also that occurring during the day, GPP can be estimated as the sum of the rates of NEP estimated during daytime, and R estimated during the night. Complicating this method are the need to account for the transfer of oxygen across the air–water interface (Gelda and Effler, 2002a) and the advection of DO in and out of the water volume measured by the sensor (Hanson et al., 2008), and spatial variability in primary production (Van de Bogert et al., 2007). The advantage of free water methods are that there will be no errors associated with incorrect experimental light exposure due to artificial containment, or a spectral mismatch between the incubator and in situ light. Furthermore, at least if the lake is well mixed, this method should potentially give a good estimate of the true NEP in the mixed layer, and avoid many of the pitfalls associated with scaling up small contained incubations to large lake volumes. (Gelda and Effler, 2002b) have successfully deployed oxygen sondes on profiling lake monitoring buoys and have developed enhanced methods for estimating NEP using vertical

profiles of dissolved oxygen concentration in order to better estimate in situ productivity throughout the entire water column. Despite the complications and assumptions associated with free water estimates of primary production, the method has gained wide acceptance and is becoming widely used to estimate lake GPP, R , and NEP. The lack of the containment affects, and power of collecting data over long time periods at high-sampling frequency has made free water methods very attractive.

LIMNOLOGICAL STUDIES IN LAKE ERKEN SWEDEN

Kurt Pettersson
 Department of Ecology and Genetics, EBC, Uppsala University, Norrtälje, Sweden

Introduction

Limnology in Uppsala has its roots in the research fields of freshwater botany and zoology. The studies of Gunnar

Lohammar on water chemistry and higher vegetation in Swedish lakes, the classic study by Wilhelm Rodhe on environmental requirements of freshwater algae, and the comprehensive zoological studies of Sven Ekman created the scientific basis of limnology at Uppsala University.

In 1928 Carl Malmén donated the Norr Malma farm to Uppsala University and established the foundation for investigation of Lake Erken and especially the conditions for its crayfish (*Astacus astacus*) population. Based on the donation, a decision was taken in 1944 to establish a limnological research laboratory including space for accommodation. The first step was to renovate an old cottage on the shoreline of the lake. In the summer of 1946, the laboratory had finally been equipped for limnological studies and the work to understand the ecological structure and function of Lake Erken (Figures 1 and 2) could start under the leadership of Wilhelm Rodhe (1946).

The Erken Laboratory of today was built 1950–1951 with support from Knut and the Alice Wallenberg foundation and renovated and enlarged in 1994. The manor building of the farm was turned into a building for lodging of students in 1951.

For more than 65 years, limnological courses and limnological research has been performed at the station with increasing intensity. Today the permanent staff is around 10 people and the analytical laboratory is certified by Swedac and limnological insights are given to more than 1,700 pupils and students yearly. The lake and its inlets are monitored on a weekly and monthly basis. A program that has run from the late 1980s to date, was based on fundamental water quality parameters. To describe the limnological studies performed in Lake Erken is an almost impossible task and I will only highlight a few examples from each decade.

The investigations of Lake Erken started already in the 1930s by Gunnar Lohammar, and Heinrich Skuja studied the phytoplankton species composition in the 1940s.

In the 1950s, Wilhelm Rodhe, Richard Vollenweider, and Arnold Nauwerck performed the first in situ measurements of phytoplankton production in lakes using the C^{14} technique (Rodhe et al., 1958). Arnold Nauwerck (1963) defended his thesis “Die Beziehungen zwischen Zooplankton und Phytoplankton im See Erken.” This was a pioneering work and the first thesis to be defended at the Department of Limnology at Uppsala University.

Wright and Hobbie published “Use of glucose and acetate by bacteria and algae in aquatic studies” in Ecology after experiments performed in Lake Erken (Wright and Hobbie, 1966). Roland Pechlaner studied the spring development of phytoplankton in the late 1960s (Pechlaner, 1970).

Ulf Granhall and Alf Lundgren continued the tradition of in situ experiments by measuring nitrogen fixation in Lake Erken (Granhall and Lundgren, 1972). Bengt Boström and Kurt Pettersson studied the spring development of phytoplankton again (Boström and Pettersson, 1977) and Kurt Pettersson defended his thesis “Orthophosphate, alkaline phosphatase activity and algal surplus phosphorus in Lake Erken” (Pettersson, 1979).

Limnological Studies in Lake Erken Sweden, Figure 1 Bathymetric map of Lake Erken, area 25 km², average depth 9 m, maximum depth 21 m.

Limnological Studies in Lake Erken Sweden, Figure 2 View of Lake Erken from the Erken Laboratory.

In the 1980s, Russel Bell followed up on the tradition of bacterioplankton studies with his thymidine incorporation measurements combined with estimations of bacterioplankton dynamics (Bell, 1984). Torbjörn Tirén and Bengt Boström followed nitrification and denitrification in lake sediments (Tirén and Boström, 1985). Richard Johnson defended his thesis “Life histories and coexistence of *Chironomus plumosus* (L.), *C. anthracinus* Zett (Diptera: Chironomidae) and *Pontoporeia affinis* Lindström (Crustacea: Amphipoda) in mesotrophic Lake Erken” (Johnson, 1986). Don Pierson made extensive measurements of primary production of phytoplankton in Lake Erken resulting in the thesis “Effects of vertical mixing on phytoplankton photosynthesis and phosphorus deficiency” (Pierson, 1990).

In the 1990s, the studies in Lake Erken increased dramatically with more than 60 publications in refereed journals. The research group lead by Kurt Pettersson, Vera Istvanovics, and Don Pierson followed the phosphorus turnover in the lake and the phytoplankton development with focus on the summertime and the cyanobacteria *Gloeotrichia echinulata* (Istvanovics et al., 1993; Pettersson et al., 1993). Russel Bell and colleagues continued their work on bacterioplankton and Katarina Vrede presented her thesis “Bacterioplankton Production and Biomass in Two Lakes of Different Trophic Status” (Vrede, 1997). Willem Goedkoop and Erik Törnblom studied the pelagic-benthic coupling (Goedkoop and Törnblom, 1996) and Gesa Weyhenmeyer investigated the sedimentation and resuspension of particles (Weyhenmeyer, 1996). Maria Kahlert focused on benthic algae and their phosphorus status and summarized her results in the thesis “Biomass and Nutrient Status of Benthic Algae in Lakes” (2001). Also dinoflagellates were studied intensively and Karin Rengefors finalized her thesis “The role of resting cysts in the Survival and Succession of Freshwater Dinoflagellates” in 1997. In 1999, Gesa Weyhenmeyer, Thorsten Blenckner, and Kurt

Pettersson published the first paper on climatic effects on Lake Erken (Weyhenmeyer et al., 1999). Don Pierson and colleagues were performing the first remote sensing studies of Lake Erken within the Salmon project (Pierson and Strömbeck, 2000).

During the 2000s, the publication rate increased even more and more than 100 papers related to Lake Erken were published. In this decade the phosphorus forms in the sediments from accumulation bottoms were followed seasonally and also coupled to sedimentation events by Willem Goedkoop and Kurt Pettersson (2000). The studies of climatic effects continued within two larger EU projects Reflect (started in the 1990s) and Clime and with Thorsten Blenckner as leading scientist, resulting in the thesis “Climate Related Impacts on a Lake” (2001). Now modeling of lake processes also became an important tool shown in the thesis of Hampus Markensten “Climate Effects on Phytoplankton Biomass and Functional Groups” (2005). The cyanobacteria *Gloeotrichia echinulata* was subject of several studies also in this decade and Irene Karlsson-Elfgren defended her thesis “Studies on the Life Cycles of Akinete Forming Cyanobacteria” (2003). Under the leadership of Helmut Hillebrand, studies on grazing and the nutrient status of the benthic community was intensified and Antonia Liess presented her thesis “Nutrient Stoichiometry in Benthic Food Webs – Interactions Between Algae, Herbivores and Fish” (2006). Also, Lars Peters studied the benthic community with focus on the meiofauna (Peters et al., 2007). This work still continues and more information will come. During the 2000s also, fish studies reappeared with Peter Eklövs’ research group studying the adaptive morphological variation in fish populations resulting in the thesis of Philipp Hirsch: “Phenotypic Processes Triggered by Biological Invasions” (2011). The invasive species *Dreissena polymorpha* and its impacts on the lake ecosystem was investigated by Rahmat Naddafi, who defended his thesis “The Invasion of the Zebra mussel – Effects on Phytoplankton Community Structure and Ecosystem Function” in 2007 (Naddafi, 2007; Naddafi et al., 2007a, b). Finally, David Lymer made a pioneering work on bacteriophages and summarized this in his thesis “Significance and Diversity of Lake Bacteriophages,” published in 2008 (Lymer, 2008; Lymer et al., 2008a, b). A list of publications from studies in Lake Erken can be found at www.ebc.uu.se/forskning/IEG/erken/.

LOCH KATRINE

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Description

It was on April 19, 1855, that the preamble of the bill, which was to municipalize the water supply to the City of Glasgow, Scotland, was passed by a Committee of the House of Commons. It had surprisingly been a hard struggle in Committee, but the bill received the Royal Assent on July 2, 1855.

Thus, over 150 years ago, a new era was inaugurated in which the supply of water to the city was so improved that it exerted a vital influence upon a rapid expansion and development of the City of Glasgow during the second half of that century. There is little doubt that the tremendous growth of Glasgow as a great industrial city is testimony to the foresight of the civic rulers in their investment in the Loch Katrine water supply scheme.

Until 1807, the citizens had to draw their water entirely from wells, or from the River Clyde and other streams, although latterly some was sold by water cart from door to door. The quality of most of the water was questionable, and it had never been adequate, especially for the fire services.

From 1807, there had followed a period of some 45 years during which no less than three private companies – The Glasgow Company (from 1807), The Cranstonhill Company (from 1808), and the Gorbals Company (from 1848) – had attempted, not very successfully, to meet the water demand of the rapidly expanding community.

The advent of Water Companies had raised high hopes that all water problems would be solved. The Glasgow and Cranstonhill Companies, pumping the water from the River Clyde and competing with each other until they merged in 1838, were never financially successful, and that in spite of the fact that pipes were laid only where the revenue was likely to show profit. In many of the less well-off districts, no pipes at all were laid, and most of the old wells were still in use although the quality of their water was continually deteriorating. The quality of the water provided by the companies, however, was often little better, owing to inferior filtration. Moreover, the expectation that the community would be better able to fight fires were not realized, for the companies refused to keep water mains charged during the night, when the danger of fire is greatest.

An outbreak of Cholera in 1848, worst in the districts not efficiently supplied with water, had added to the growing dissatisfaction with the efforts of the companies.

Public opinion, however, had been converted gradually to the idea that the supply of water was too important a service to be left to the control of private investment. In time, the city council was converted to the same view and, on October 28, 1852, approved a resolution to take the necessary steps to bring the water supply of the city into the hands of the council, as a public trust. In December of the same year, the council secured the services of the eminent civil engineer John Frederick Bateman to advise as to the best sources of new supply. Bateman's work both at home and abroad was mainly concerned in the design and preparation of water supply schemes and also in an advisory capacity. He had already performed these tasks successfully in Manchester and Buenos Aires and in other areas.

By September 1853, Bateman had reported on seven possible schemes, one of which he recommended the Loch Katrine scheme as the only one which would meet all the requirements. How ambitious and far-sighted was this scheme may be judged from the fact that it provided for abstracting as much as 50 million gallons per day (mgd), or 220 MLD (million liters per day), whereas consumption at that time was only 14 mgd (60 MLD).

The council accepted the recommendation, however ambitious it may have seemed, and proceeded to promote the necessary bill in Parliament.

Opposition was expected from the private companies, from the landowners, and even from important sections

of cautious ratepayers (taxpayers), but the Council was hardly prepared for the argument that led to its first setback, namely that the extreme purity and softness of Loch Katrine water would constitute a real danger to health of the community because its action on lead pipes would give rise to lead poisoning. A special enquiry by scientific experts had to be made and most elaborate tests carried out before this fear was proved groundless. The admiralty then appeared in opposition, alleging that the abstraction of so much water, which would normally flow into the Firth of Forth, would seriously affect the influence of a navigable channel. This opposition proved the death-blow of the bill, which was forthwith rejected.

The Lord Provost and the Water Committee of the city council refused to accept defeat and prepared a new bill for promotion at the next session of Parliament and took all steps to remove opposition.

So successful were the measures adopted that when the new bill came before the Committee of the Commons in April 1855, the proceedings – having regard to previous experience – were somewhat of an anti-climax and there was no opposition.

Although the Act of 1855 was concerned mainly with the new source of supply from Loch Katrine, provision was also made for taking over the existing works of the private companies. Of the Glasgow Company's works, only certain sections of the city could be incorporated in the new system, and the greater part, including the pumping plant, reservoirs, etc. had to be abandoned. The Gorbals works near Barrhead, however, being modern, were retained.

The Loch Katrine scheme involved the construction of (1) masonry and earth dams across the outlets of Loch Vennachar, Loch Drunkie, and Loch Katrine, in order to secure the storage required to guarantee both the supply to the city and compensation obligations, (2) an aqueduct 28 miles (45 km) long from Loch Katrine to Milngavie, (3) Mugdock Reservoir at Milngavie, and (4) the laying of about 20 miles (32 km) of large trunk main from the reservoir to the city and about 46 miles (74 km) of new pipes for distributing the water throughout the city and suburbs. Loch Katrine is 364 ft (111 m) above the tide at Glasgow – an elevation that allows for the loss of fall in the conveyance of the water and still ensures a pressure of 70–80 ft (21–24 m) above the highest summit within the city.

The construction of these works was an undertaking of considerable magnitude, and their completion within a period of 3½ years, having regard to the difficulties encountered and the equipment then available, was a remarkable civil engineering achievement. Work commenced on May 29, 1856, upon the construction of the aqueduct, and on October 14, 1859, Her Majesty Queen Victoria, accompanied by The Prince Consort and The Princesses Alice and Helena, came through from Holyrood Palace by way of Stirling and Callander to open this great civil engineering work. She sailed up the Loch from Trossachs Pier to Stronachlachar and Royal Cottage

(so named after her visit). It had rained during the morning but cleared for the occasion. In her speech she said:

It is with much gratification that I avail myself of this opportunity of inaugurating a work which, both in its conception and its execution, reflects so much credit on its promoters, and is so calculated to improve the health and comfort of your vast population, which is rapidly increasing round the great centre of manufacturing industry in Scotland. Such a work is worthy of the enterprise and philanthropy of Glasgow and I trust it will be blessed with complete success. I desire that you will convey to the great community which you represent my warmest wishes for their continued prosperity and happiness.

After a prayer of dedication and thanksgiving, Her Majesty turned the handle placed for the purpose, and, amid the booming of cannon repeated at the Trossachs and Callander, the Loch Katrine Water Works were declared duly inaugurated. The news was telegraphed to Glasgow, Edinburgh, and Stirling. Edinburgh and Stirling castles at once sent forth their salvos of artillery, and in Glasgow, the city bells rang merrily in celebration of the event. At Her Majesty's request, the royal party was conducted at the sluice, so that they might themselves see the water flowing for the first time from Loch Katrine toward Glasgow – there to begin the beneficial work of safeguarding the health of the community and stimulating the development of the city and its industries.

At a Banquet given in his honor to commemorate the completion of the Loch Katrine Water Works, Bateman said in his speech:

I leave you a work which I believe will with very slight attention, remain perfect for ages, which, for the greater part of it, is as indestructible as the hills through which it has been carried: a truly Roman work. Not executed, like the colossal monuments of the East, by forced labour at the command of an arbitrary Sovereign, but by the free will and contributions of a highly civilised and enlightened City. It is a work indeed which surpasses the greatest of the nine famous Aqueducts which fed the City of Rome; and amongst the works of ornament and usefulness for which your City is now distinguished and will hereafter become famous, none, I venture to say will be counted more credible to your wisdom, more worthy of your liberality, or more beneficial in its results, than the Loch Katrine Water Works.

The population of the city enjoyed their bountiful supply of wholesome water, but the story is told of an old lady who lived in Monteith Row and who, all her life, had been in the habit of carrying all the water she required from the Arns Well in Glasgow Green, a practice she insisted in continuing even after the Loch Katrine supply was available. When the authorities decided to close Arns Well, which had become polluted and a menace to public health, she was very indignant and complained bitterly to a neighbor who tried to soothe her by saying "Hoots woman why need you fash yourself you've got gravitation water in the house," to which the old dame retorted "Huh, I just canna thole that new water, it's got neither taste nor smell."

The event was of national interest and "Punch" even produced an article:

Glesca's just a' richt the noo,
She has Loch Katrine brought her,
Ever she had mountain dew,
Noo she rins wi' mountain water.
Hech the blessin'! ho the boon!
Tae ilka drouthie Glesca body,
Sin' there's water in the toon
Owre eneuch to mak its toddie.
Glesca chiels, a truth ye'll learn
New to mony a Scot, I'm thinkin'
Water siblins ye'll discern
Was na gi'en alone for drinkin'
Hauns and face ye'll scrub at least,
Frae ane until anither Monday,
Gif nae Sabbatarian bust
Stop your Waterworks on Sunday

In only 12 years later, consumption had almost reached the design figure of 14 mgd (60 MLD) that according to estimates should not have been reached until 1,900. There was no doubt that the new abundant water supply was an important factor in the development and growth of the city. It was also found that the aqueduct could carry only about 40 mgd (180 MLD) instead of the estimated 50 mgd (225 MLD). A substantial extension of the works became urgent. The necessary parliamentary powers were secured by the Acts of 1882 and 1885 to:

1. Construct a second service reservoir at Craigmaddie
2. Construct a second line of aqueduct from Loch Katrine to the reservoir in Milngavie
3. Increase the storage capacity of Loch Katrine by a further raising of the level by 5 ft (1.5 m)
4. Impound the waters of Loch Arklet and convey them into Loch Katrine through a connecting aqueduct
5. Increase the maximum quantity that might be drawn from Loch Katrine to the city in any 1 day from 50 mgd (225 MLD) to 110 mgd (500 MLD)
6. Lay two additional trunk mains from Milngavie Reservoirs to the city

By the completion of these works in installments by the year 1914, the storage capacity of Loch Katrine and Loch Arklet and the aqueduct delivery capacity were more than doubled, and ample provision seemed to have been made for many more years.

By the year 1911, the population supplied had increased to over one million and the average daily consumption to nearly 68 mgd (310 MLD). Over the previous 30 years, this represented an increase in population of 50% and in consumption of about 75%. It was therefore clear that the existing storage would not be adequate for any further great increase in demand, and a new problem thus presented itself. Two solutions were found and approved by the Glasgow Corporation, one a more permanent solution and the other an interim one. For various reasons the interim was proceeded with first.

The interim solution involved a further and third raising of the level of Loch Katrine and the inlet at Royal Cottage

by 5 ft (1.5 m). With these works completed and with the loch at its new top water level, the undertaking could draw upon a depth of 17 ft (5 m) instead of the original 7 ft (2 m), providing a storage capacity sufficient to supply the city with water for a period of 7 months without rainfall on a consumption basis of 70 mgd (320 MLD) or 5½ months at the then present consumption of approximately 90 mgd (410 MLD). Although storage in Loch Katrine and Loch Arklet would be three times the original capacity under the 1855 Act, the yield of the drainage area had not been in any way increased.

For the more permanent solution, a new source of supply which would increase the available yield of water was essential, and in 1914, a bill was promoted to impound the water of Loch Voil and Loch Doine and convey to Loch Katrine by tunnel. The unfortunate rejection of this scheme by the Parliament is a matter of history. It was a bold, ambitious, and far-sighted scheme, which, had it materialized, would have provided an additional 58 mgd (264 MLD) and would have solved all problems of water resources for many years.

An alternative source was ultimately found in Glen Finglas, and, by the Act of 1915, powers were secured to impound the Rivers Turk and Finglas by the construction of a dam, thus creating a reservoir with a capacity greater than that of Loch Arklet, although considerably less than that of Loch Voil. Unfortunately because of the First World War, the work could not be started, and by 1918, prevailing high costs dictated the adoption of the above interim solution and this was finally completed in 1926.

The long period of industrial depression between the two World Wars caused the Glen Finglas scheme to be kept in reserve as a prudent provision for future needs.

It was 30 years before demand again reached the peak demand, and in the intervening depression years, it dropped to 11 mgd (50 MLD) below the peak. Then partly due to improved distribution, attributable to extensive new works of the post war period including the Clyde Water Tunnel, the demand curve began to rise steeply, the Chief Water Engineer and General Manager recommended an early start to the Glen Finglas Scheme, albeit a modified scheme.

The modified scheme provided surplus water from the Glen Finglas intake weir across the River Turk and a tunnel to Loch Katrine and later the construction of the dam at Glen Finglas.

The first part was completed and inaugurated on October 23, 1958, by HRH The Princess Margaret.

The second part, that of the dam, was completed in 1965. The dam is 115 ft (35 m) and 800 ft (243 m) at crest level, creating a storage of 3,500 million gallons (15,900 million liters) supplying an average of 20 mgd (91 MLD) to Loch Katrine through a horseshoe tunnel 8 ft (2.5 m) in diameter laid to a gradient of 1 in 3,000 about 2½ miles (4 km) long. The tunnel driving was limited to two headings, one from each end, and the junction of the discrepancy of the two headings was less than ¼ inch (6 mm) in line and level. Control of the tunnel drive was exercised by means of roof stations set in by theodolite and level. These were used by the tunnel gangers to mark out the position of the shot holes for each round of explosive. It was necessary to make a comprehensive triangulation survey across the hills with measured base lines in Glen Finglas and at Loch Katrine to ensure that the two tunnel headings would meet successfully. The rock encountered in the tunnel was mainly metamorphic grit and schist, and the tunnel was dry on the whole.

Loch Katrine, Figure 1 View of Loch Katrine from Ben A'an (Scottish Water).

As the population of the city reduced in the subsequent years, from the original high in the 1930s of 1,250,000 to eventually 700,000 in the 1980s, there was little need to consider new or additional sources, this in spite of the closure of the Gorbals works near Barrhead.

However, there was a need to consider the water quality of the Loch Katrine supply which had, from its inception, required no treatment, the quality being such that only disinfection by chlorination was necessary and that only apparently necessary since the 1930s.

In addition, reorganization of the water industry in Scotland in the 1990s saw the whole of the water industry in Scotland coming under Scottish Water. Investment was required to modernize the industry and for the need to upgrade the treatment of water, in particular, for microorganisms or bacteria and cryptosporidium, to meet the UK and European Standards (European Directives and WHO Standards). Indeed, the city suffered a cryptosporidium contamination in 2002 when 160,000 people were told to boil their water after bacteria got into the supply. The treatment works at Milngavie is scheduled to be completed in 2007 including the construction of a 240 MLD (50 mgd) direct filtration plant, modification to the existing Balmore Water Treatment Works pumping station to allow the conjunctive use of 150 MLD (30 mgd) into the Glasgow supply area, and other ancillary work.

The Balmore Water Treatment Works was completed in 1997 for treating water from the new Loch Lomond source to serve other areas of Scotland. The Loch Lomond Aqueduct conveys a pumped raw water supply of 286 MLD (60 mgd) to the treatment works. The two aqueducts cross each other north of Milngavie (the 400 MLD (88 mgd) supply from Loch Katrine and the 286 MLD (60 mgd) from Loch Lomond). In order to allow the conjunctive use of 150 MLD (30 mgd) from Loch Lomond into the Glasgow supply, a cross connection was made. Thus, the final link will be in place to continue the 150 years of investment in Loch Katrine water (Figure 1).

LOUGH

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Lough

Lough is an anglicized form of loch which is Irish Gaelic (pronounced Gailik). Loch is entirely used in Scotland with one exception – the Lake of Menteith near Aberfoyle. Lough is used in Ireland almost exclusively. It was

introduced by British administrators as the anglicized form of loch, but lough is also used for some water bodies in the north of England.

Lough Neagh in Northern Ireland is the largest lake in Ireland and the largest in area in the United Kingdom. The three lakes on the Shannon are Lough Allen, Lough Ree, and Lough Derg.

LOUGH NEAGH

Reginald W. Herschy¹, P. G. Holland (Deceased)

¹Hydrology Consultant, Reading, UK

Location

Lough Neagh is located in Northern Ireland with its geometric center at latitude 54° 36'N and longitude 6° 23'W. Its Irish grid map reference is J 3032 3750. Politically, it is totally within the United Kingdom, although some of its contributory rivers have sources in the Republic of Ireland.

Physical parameters

Six major rivers flow into Lough Neagh: the Main, Six Mile Water, Upper Bann, Blackwater, Ballinderry, and Moyola. There is one outflow: the Lower River Bann which flows into the sea. The Lough Neagh and Lower River Bann Basins include 43% of the surface area of Northern Ireland and about 30% of the Northern Ireland population. The two Basins are predominantly agricultural in character, but there are areas of significant population in Craigavon, Antrim, Ballymena, and the Coleraine–Portrush–Portstewart triangle. There are no nationally important industries, but there are numerous locally based industries which, collectively, contribute measurably to the overall United Kingdom economy. The water surface area of Lough Neagh is 385 sq. km, making it the largest lake in extent in the British Isles. The inflowing catchment area is 4,465 sq. km and the outflowing basinal area is 925 sq. km: a combined area of lake and basins of 5,775 sq. km. The Lough has a maximum depth of about 30 m, an average depth of 9.5 m and a total capacity of about 3,636 million cubic meters.

The geological structure of the area is of a folding and faulting nature, formed in Tertiary times to some 450 m of chalk layers, immediately after the outpourings of the East Antrim basalts. Most of the area is overlain by glacial deposits (mainly boulder clay) with more recent deposits of mainly river gravel (Figure 1).

Flow regime

The flow regime is controlled artificially by vertical sluice gates, of which there are three separate installations. At the outlet from the Lough, gates, built on a rock outcrop, control the Lough level to a statutory requirement of between 15.24 and 15.39 m above the mean sea level, provided that climatic excesses do not make that preciseness of control impossible. The effective control of the Lough outflow

control and monitor because they are either concentrated discharges from animal or poultry units, or runoff and seepage from land which has been either organically or inorganically treated. Toxic waste can pose a threat, but waste disposal measures generally preclude toxic discharges to watercourses.

Eutrophication always has been looming in Lough Neagh because of its slow volumetric turnover time of about 12 months and its predominantly shallow depth below a relatively large surface area. The major eutrophication-inducing factor has been the phosphorous loadings emanating from sewage treatment works and agricultural sources, but this aspect has been reduced significantly by heavy expenditure on tertiary treatment of sewage and on isolating agricultural discharges wherever this has been practical. The Lough cannot be classified as eutrophic, but continuous monitoring is undertaken to guard against adverse trends toward eutrophication.

Sedimentation

This is not a particularly prominent facet of Lough Neagh or any of its basins. Normal erosion does take place in the rivers, of course, but it is not of such a magnitude that watercourses change their profiles or that very much remedial work is needed to protect banks and adjacent property. Dredging requirements are minimal. The regolith material from the inflowing rivers settles mostly, eventually, in the Lough, and in the deepest parts there are sand and gravel deposits that are commercially very valuable and providing a major proportion of the sands and gravels used industrially in Northern Ireland.

Usage

Basically, Lough Neagh and its basins are underused but the following uses do prevail.

Fisheries: The important fish are the salmon and the eel, both migratory and supporting viable commercial ventures. Salmon enter the river system from the sea in May, June, July, and August and are subject to netting at the tidal estuary of the Lower River Bann and to trapping at the two sluice structures in the river. Further upstream and in the Lough, some angling and fishing from boats take place. Eels, after spawning in the western Atlantic Ocean, move into the Lower River Bann when 3 years old from March to May, and travel back to the spawning grounds when 8 years old or more. On both journeys, they are caught commercially for major marketing ventures in Great Britain and in the Netherlands.

Water supplies: Approximately two-thirds of the public water supplied to the Belfast conurbation and its contiguous areas are drawn from Lough Neagh. In addition, public water is taken into the northeastern areas of Northern Ireland and into the Craigavon area. Treatment is at source, at a level or purity which more than satisfies the standards set by the EU. The amounts taken are substantial, but nevertheless, are very small in relation to the total volume of water in the Lough. Future increases in water

supplies to the general Belfast area would be provided for by additional abstractions from the Lough.

Drainage: The Lough and its basins are natural gravitational drainage areas so that flooding virtually is nonexistent. The statutory controls of the Lough surface levels emanate from successive lowerings of the Lough by some 2 m which released an additional 20,000 ha of peripheral land for agricultural usage.

Navigation: The Lower River Bann is navigable by small craft for its whole length as navigation ways are provided at all three sluice structures. The Lough itself is used for sailing, but the amount of sailing undertaken falls far short of the enormous potential for the activity which the Lough could provide.

Tourism and Recreation: As with the sailing, the potential is not realized anywhere near to the full extent. Market forces do not attract extensive tourism to Northern Ireland and the relatively low population density of Northern Ireland means that the number of people seeking recreational facilities in the Lough Neagh area is not very large.

Nature Conservation: There are several areas of scientific interest around the Lough and some areas of natural beauty; all overseen admirably by relevant Government agencies.

Management

Surprisingly, there is no overall management authority for Lough Neagh and the two basins. Management of the various interests is vested mostly in relevant Government Departments and Agencies, who accept their responsibilities generally with both diligence and enthusiasm. However, these authorities operate from a variety of resource bases, which make it difficult to get a consensus for the acceptance of the proportioning of contributions toward the cost of creating and operating a Lough Neagh Conservancy or similar body. Considerable progress toward the creation of a single management body has been made but that ultimate goal has yet to be achieved.

M

MACEDONIAN LAKES

Stanislava Dodeva
Skopje, Macedonia

Introduction

The Republic of Macedonia is a land-locked country located in the central part of the Balkan Peninsula, covering an area of 25,713 km², with about two million inhabitants and with annual water resources per capita of about 3,150 m³.

From the hydrographic aspect, the territory of Macedonia is a unique natural basin in the Balkan Peninsula and wider because more than 80% of the water resources are formed on the territory of the country in four river basins: Vardar, Crn Drim, Strumica, and Juzna (South) Morava river basin. The river basin areas of Vardar and Strumica River gravitate toward the Aegean Sea, covering 87% of the total territory. The river basin area of Crn Drim River gravitates toward the Adriatic Sea (13% of the total area), and the river basin area of Juzna Morava whose territory is insignificant gravitates toward the Black Sea.

There are three major natural lakes in Macedonia: Ohrid, Prespa, and Dojran Lake. The locations of these lakes are shown in the map in [Figure 1](#). All of them are shared with the neighboring countries. The lakes belong to the group of the oldest European tectonic lakes.

Ohrid lake

General

Lake Ohrid is the biggest lake in the Republic of Macedonia and is located in the southwest part of the country, on the border between Macedonia and Albania. It is situated on 695 m.a.s.l., and it covers an area of 358.2 km², out of which 230 km² belongs to Macedonia

and the rest to Albania. The total watershed area covers 2,340 km², out of which 843 km² belongs to Macedonia. The shoreline is 87.5 km long, out of which 56 km belongs to Macedonia, the maximum length is 30.8 km, and its maximum width is 14.8 km. The average depth is 164 m and maximum depth is 289 m.

The Lake is surrounded by the mountains Mokra (Mokra Planina – 1,589 m.a.s.l.) and Jablanica (1,945 m.a.s.l.) on the Albanian side, as it is shown in [Figure 2](#), and by the karstic mountain Galicica (2,255 m.a.s.l.) on the eastern side.

History

Lake Ohrid is Europe's oldest lake (between 4 and 10 Ma ago) and is among the oldest in the world. By its origin, the Lake is a tectonic lake and belongs to the so-called group of "Desaretian lakes," named by an ancient region Desaretia. The Lake was formed in the tertiary period prior to the glaciation.

Due to rich history and unique flora and fauna, Lake Ohrid was declared a UNESCO World Cultural and Natural Heritage Site in 1980.

Geology

The wider zone in this part of the country consists of a complex of Paleozoic metamorphic and magmatic rocks which makes up the foundation bedrock. The Mesozoic rocks from the Triassic Era show types of faces, such as (1) sediments consisting of conglomerates, sands, and clays and (2) carbonate sediments, such as slate, bank and massif limestone, and dolomites. These sedimentary formations are intensely rugged, broken, and karstified. Tectonic forces formed much of the terrain in the Lake Ohrid watershed. It has been shaped by both Hercynian and Alpine orogenesis.

Hydrographic features

Lake Ohrid is the seventh deepest lake in Europe, with a volume of 50.7 billion cubic meters. Most of the water

Macedonian Lakes, Figure 1 Map of Macedonia.

comes from numerous surface and underground springs. The surface springs mostly lie along the southern shore on the Macedonian side at location St. Naum (average $7.5 \text{ m}^3/\text{s}$) and close to city of Podgradec in Albania (average $2.5 \text{ m}^3/\text{s}$). There are about 40 rivers and springs which flow into the Lake (23 on the Albanian and 17 on

the Macedonian side). During summer, most of them dry out, whereas the rivers Sateska (average $6.2 \text{ m}^3/\text{s}$), Koselska (average $1.3 \text{ m}^3/\text{s}$), and Corava (average $1.5 \text{ m}^3/\text{s}$) have significant inflow that charges the Lake. On the Albanian side, the river Podgradeci has an average discharge of $0.3 \text{ m}^3/\text{s}$.

Macedonian Lakes, Figure 2 Ohrid Lake.

In the beginning of the previous century, J. Cvijic stated the assumption that the water of the adjacent Lake Prespa, which has 158-m-higher water level, flows through the karstic areas of the mountains Galicica and Suva Gora. The two lakes formed one lake at their earliest stage of existence. By using natural isotopes, it has been proved that these two lakes are connected hydrographically. Evidence has confirmed that more than 50% of the water from the springs near St. Naum comes from Lake Prespa. The discharge of the karst water coming out of Galicica Mountain is $5.2 \text{ m}^3/\text{s}$.

The Lake has one outlet, the River Crn Drim, which flows to the Adriatic Sea. This outlet is man controlled, and according to the needs of the downstream power plants, it provides about $22 \text{ m}^3/\text{s}$ or a total annual outflow of 694 million cubic meters. Downstream, there are two dams on the Macedonian territory and three on the Albanian side, with a main purpose – energy production.

Climate

The climate of Lake Ohrid is classified as a local-continental type. Mean annual air temperature is 11.4°C . The average annual rainfall in the Lake basin is about 759 mm. The water temperature in the deepest layers of Ohrid Lake is approximately 6°C , while the surface layers may have up to 24°C , and even up to 26°C closer to the shore. The Lake never freezes over.

Flora and fauna

Due to the low level of nutrients, the lake is classified as oligotrophic lake. This Lake is distinctive shelter of large number of freshwater organisms originating from the tertiary period, whose close relatives can be found in fossil forms only. Due to the geographic isolation and permanent living

conditions, the existing tertiary living forms further evolve into new taxonomic classes, including subspecies, species, and even entire families of newly evolved organisms. For this reason, the lake is also called “museum of living fossils.”

Most of the endemic species are benthic forms (e.g., *Pyrgula macedonica* (freshwater snail; Stankovic, 1960), *Ochridaspongia rotunda* (freshwater sponge; Gilbert and Hadzisce, 1984)), but there are also a number of endemic plankton species (e.g., *Cyclops ohridanus* (zooplankton) and *Cyclotella fottii* (phytoplankton) both described by Stankovic (1960), as well as fish (e.g., *Salmo letnica* [Ohrid trout; Sell and Spirkovski, 2004])).

The fish population of the Lake comprises 17 native species belonging to four families: *Salmonidae* (2 species), *Cyprinidae* (12 species), *Cobitidae* (2 species), and *Anguillidae* (1 species). One of the most fascinating species in the lake is the European eel, which comes to Lake Ohrid from the distant Saragossa Sea. Due to constructed dams on the river Crn Drim which stopped the migration of eels, the reproduction is enabled with providing young eels directly into the lake from other sources.

The lakeshore reed beds and wetlands provide critical habitat for hundreds of thousands of wintering water birds, including rare and threatened species, such as the Dalmatian Pelican, Ferruginous Duck, swan, Spotted Eagle, and Eastern Imperial Eagle.

The Lake's flora is dominated by various types of algae and superior water plants. Typical for this lake is the underground plant called “hara” that forms a continual ring in the lake's bottom at the depth of 6–15 m.

Cities

There are three cities on the Lake's shores: Ohrid and Struga on the Macedonian side and Podgradec on the

Albanian side, with total number of about 200,000 inhabitants (in 2003). The main economic activities in the region are tourism and agriculture.

Prespa lake

General

There are two lakes in the Prespa valley: Big Prespa Lake and Small Prespa Lake. Big Prespa Lake is shared among the Republic of Macedonia, Albania, and Greece. It has a surface area of 274 km², out of which the bigger part (65%) belongs to Macedonia, the southeast part (about 17%) belongs to Greece and southwest part (about 18%) belongs to Albania. Maximal length of Lake Prespa is about 28 km, maximal width is about 17 m, and the average width is about 10 km. Maximal depth of Lake Prespa, according Cvejic in 1911, is 54 m, but during this period, it has been less than 50 m deep, while the average depth is between 15 and 17 m. Small Lake Prespa belongs fully to Greece. The location of the lake is shown on the map in Figure 1, while Figure 3 presents the satellite image of both lakes.

They are the highest tectonic lakes on the Balkans, standing at an altitude of 853 m.a.s.l. There are two islands in Big Prespa Lake: “Golem Grad” (also called St. Peter) and “Mal Grad” (also called St. Paul). The island “Golem Grad” is declared for a reservation, for its specific geomorphology, its flora and fauna, and its historical past.

History

Lake Prespa, together with Lake Ohrid, is between the oldest lakes (2–3 Ma) in Europe that, according to Cvijic's (1911) estimation, originated from Pliocene period. These

Macedonian Lakes, Figure 3 Satellite image of Prespa Lakes.

two lakes are not linked on the surface, but the water from Lake Prespa through the karstic area of the mountain Galicica flows into Ohrid Lake (Anovski et al., 1980).

Geology

Lake Prespa has tectonic origin and fulfills the deepest part of Prespa valley. It is located at the touch of three different geological masses, the granite massif on the east side Pelister, karstic massif of Galicica on the west, and Suva Gora (Dry Mountain) on the south side. The Ohrid–Prespa region is characterized by very complex geological-tectonic structure where rocks, from the oldest Paleozoic formations to the youngest Neogene and Quaternary, have been represented. The terrains which make this region belong tectonically to the west Macedonian tectonic zones within the Dinarides (Helinides) formed in the period of Hercynian and the Alpine orogenesis.

From hydrogeological aspect, all types of aquifers have been presented (confined, scattered, and karst type), but the most significant is the karst type of aquifers, of which the mountain Galicica has been formed as horst-anticlinorium between Prespa and Ohrid Lake, with numerous represented karst forms, such as karst fields, sinks, and sinkholes, as well as the underground channels significant for the genesis of Ohrid and Prespa Lake.

Hydrographic features

Watershed of Lake Prespa is about 1,200 km². Main tributaries that feed the lake are the rivers Istocka, Golema, Pretorska, and Brajcino River on the Macedonian side and river Stara in the Greek part of the watershed. Total volume of Lake Prespa is 4.8 billion cubic meters. Through the karstic area of the mountain Galicica, the water from this Lake flows into Lake Ohrid. There is no surface outflow from Lake Prespa.

Natural oscillations of the level of Lake Prespa are characteristic and, according to Cavkalovski (1977), appear every 20–25 years. For the period 1961–1986, there were average oscillations of the water level, but from 1986, the water level started drastically to drop-down; the absolute annual minimum of the water level of –445 cm occurred in 2002. This extreme reduction of the water level is resulting due to the anthropogenic impact (use of the water from the lake for irrigation purposes) as well as due to the climate change. The records of the water level for the last few years show increase of the water level and stabilization of the water balance of the lake.

Climate

In the Lake Prespa watershed, the following types of climate appear: warm and cold sub-Mediterranean climate; submountainous and mountainous sub-Mediterranean climate; and, on the highest elevations, respectively, subalpine and alpine climatic types. The average annual air temperature is about 9.5°C for the city of Resen, while the average annual water temperature of the lake is 13°C, with a maximum temperature of 22°C in August and a minimum of 4°C in February. Average annual sum

of precipitation around Lake Prespa is about 600 mm. During extremely cold winters, upper littoral zone of Lake Prespa freezes, although for a short time.

Flora and fauna

There is high habitat diversity in the Prespa basin, with a flora of more than 1,500 species. The indigenous fish species are all endemic, while endangered mammals include brown bear *Ursos arctos*, wolf *Canis lupus*, chamois *Rupicapra rupicapra balcanica*, and European otter *Lutra lutra*. The area is especially important for water-birds, notably the largest breeding colony of Dalmatian Pelicans *Pelecanus crispus* (listed by IUCN and BirdLife International as Vulnerable) in the world as well as a substantial number of White Pelicans *P. onocrotalus* and Pygmy Cormorants *Phalacrocorax pygmaeus*. Since 1994, the strict natural ornithological reserve EZERANI has been promoted with its inclusion on the world Ramsar list. Regarding fish, Lake Prespa is not very rich with fish. Among the six endemic species of fish, the Prespa bleak (*Alburnus belvica*) and the carp (*Cyprinus carpio*) are the most important.

Population

In the Prespa Lake watershed, there are 5,000 inhabitants in 12 villages on the Albanian side, 1,600 inhabitants in 13 villages on the Greek side, and about 17,500 inhabitants on Macedonian side, situated in 40 settlements. The biggest settlement in Macedonia is the city of Resen as administrative center of the municipality. The main activities of the population are agriculture (dominated by fruit production in Macedonia), tourism, fishing, and food processing industry.

Dojran lake

General

Lake Dojran is the smallest tectonic lake in Macedonia, situated in the southwest part of the country, occupying an area of 43 km². The western, larger part (27 km²) belongs to Macedonia, while the eastern, smaller part (16 km²) belongs to Greece. The water level of the lake is at 148 m.a.s.l. The lake is rather shallow, and the deepest part is about 10 m. The shallow character of the lake is visualized in Figure 4. On the north, the basin of the lake is enclosed by the mountains Belasica and Boska; on the west, with the mountains Dub and Kara Balija; east, Krusa; and on the south, is opened to the valley of the river Gjolaja and toward the Thessalonika Plain.

History

The Lake Dojran basin was created during the young Pliocene, while the lake was created in Pleistocene. Actually, Dojran Lake is relict reminder of former Pleistocene Peon Lake, which was occupying an area of about 127 km².

Geology

Dojran Lake and wider area are located on the boundary areas of two large geotectonic units, actually on the border between the Serbian-Macedonian massif on the east and Vardarian zone on the west. Terrain of this region is made of Precambrian, Paleozoic, Mesozoic upper Eocene, and Neogene's Quaternary.

Hydrographic features

The Lake is filled with water through underground springs and from Golema Reka, Toplec, and other rivers. The

Macedonian Lakes, Figure 4 Dojran Lake.

Lake flows out through the river Gjolaja on the Greek territory if certain level of the water is achieved. The total watershed covers the area of 272 km², out of which 92 km² belongs to Macedonia, while 180 km² to Greece.

The level of Lake Dojran has dropped considerably during the period from 1988 to 2000. Individual lake zones and groups of species were endangered. Birds were threatened first due to drying up of the reed belt which was the most important nesting place for birds. The main reasons for this level decrease were the extraordinary dry years and overexploitation of the water for irrigation from both the Macedonian side and the Greek side.

In the period from 1988 to 1995, the depth of the lake was reduced to 4 m. In the same period, the annual sums of the rainfalls were only 80% of the average multiannual sums of rainfalls. This was reflected also in the lost of water volume of the lake from 229.3 million cubic meters in 1988 to 85 million cubic meters in 1995, which means that only 38% of the original volume of the lake was still existing. The surface area of the lake was reduced to 79% of the starting surface area (Skoklevski, 2003).

In order to save Lake Dojran, the Macedonian authorities in 2002 put under operation a system for recharging of the lake with groundwater. The groundwater is abstracted from 10 wells in the area of Gjavato Pole, with total capacity of 1,000 l/s, and transported by 20 km of pipeline toward Lake Dojran. The results are already positive, and together with improved hydrological conditions, the water level started to rise.

Climate

The watershed of Lake Dojran has sub-Mediterranean climate with higher monthly average air temperatures and lower sums of annual rainfalls. The average annual air temperature is between 13°C and 15°C, while the average annual sum of rainfalls is 620 mm.

Lake Dojran is the warmest natural lake in Macedonia. The water temperature of the lake goes up to 27°C in August and up to 6°C in winter period.

Flora and fauna

Lake Dojran is a eutrophic lake rich with phyto- and zooplankton. The blue-green algae (Cyanophyta) are the most abundant in the phytoplankton. During August and September, their biomass is so large that the whole lake surface is covered by water bloom. Zooplankton is represented by 23 crustacean and several shell species. Due to the high plankton production, Lake Dojran is rich with fish species (about 15 species; 4 of them, endemic). The presence of freshwater crab (*Potamon ibericum*) is very significant.

In the period of the drastic drop-down of the lake, accelerated eutrophication has led to intensive sedimentation and a dramatic reduction in the epibenthic communities, as well as serious changes in the structure of the algal microflora. Although currently severely disturbed, the benthic community likely still has enough genetic potential to completely restore itself.

Cities

There are only two settlements on the Macedonian side, Star and Nov Dojran, with total population of about 3,700 inhabitants. On the Greek side of the lake, there is one settlement, Dojrany, with similar number of population. The main activities of the inhabitants are tourism and fishing. Fishing on the lake is done in a primeval way with the help of birds and is a unique way of fishing in the world. The birds, by their presence, make the fish to enter into the special bounds of cane called "mandri" from which the fish cannot escape.

Dams and Reservoirs in Macedonia

MARACAIBO LAKE

Rhodes W. Fairbridge (Deceased)

Definition

Lake Maracaibo is a large lake of mixed brackish marine and freshwater origin, located in the NW part of Venezuela covering about 13,510 km². It is about 213 km long and up to 115 km across. It was discovered in 1499 by Alonso de Ojeda, who named the country "Little Venice" because of the thatched huts on stilts around the lake shore. It is one of the world's great petroleum producers, where oil was discovered in 1917. Today the horizon is studded with offshore oil derricks.

The lake is shallow, an area of tectonic subsidence. Its depth is 35 m in places, and it is connected to the ocean via Tablazo Bay and the Gulf of Venezuela to the Caribbean.

Ocean-going tankers cannot negotiate the shallow strait and need to be loaded at the city of Maracaibo. The lake is fed by the Catatumbo River, which rises in the Cordillera Oriental of Colombia.

MARIB DAM AND IRRIGATION PROJECT

Rajib Chakraborty

Water Resources Department, Consulting Engineering Services (India) Pvt. Ltd., New Delhi, India

The glorious past

The Republic of Yemen is situated in the southern fringe of the Arabian Peninsula. It is considered a most attractive country to the tourists from around the world for its excellent scenic beauty and archeological heritage. The Marib region is located at the eastern part of the country and was an ancient historical glory of Arabian Peninsula with a highly developed agricultural economy (Figure 1). The Marib capital of Shebans, the religious and political center of the kingdom, was the place where both intellectual and material evolution originated as well as culminated. It was here that the most perfect specimen of an ancient irrigation system was constructed, being a complex and technically highly elaborate project. The Marib dam, across Wadi Abida at the mouth of the Jabal Balaq gorge, was one of the world's oldest manmade dams constructed about the sixth century B.C. (Figure 2).

The dam was a diversion structure having a small storage capacity and was the largest of a series of smaller dams built during later centuries. The smaller dams were built by the local people to divert water to their fields. The old Marib dam was about 14 m in height. The dam was silted up in the course of time with sand and sediment load brought in by the wadi (wide-bedded river) waters. The old dam was affected by heavy floods and also had

undergone recurring processes of reconstruction. The catastrophe, which occurred toward the end of the sixth century A.D., damaged the dam irreparably. This incident is described in the Holy Quran as the "Mighty Deluge." The remnants of the old Marib dam and Sheban civilization can be seen in the vicinity of the project area. The Marib region, therefore, is invested with archeological heritage and attracts tourists and archeologists from around the world.

Development of the project

The structure of Marib's society is based on a tribal system. Five to six main tribes live here and dominate the area. In tribal law, the head of the tribe (Sheikh) is the most powerful man and the decision maker. The old way of spate irrigation was to utilize the flood by diverting it to agricultural land by constructing bund across the widespread river (wadi). According to tribal irrigation law, the upstream farmers retain the water for a certain time period; then, they are obliged to release to their neighbors downstream and so on until the water is completely infiltrated. Erratic rainfall in the area and gradual extension of agricultural land obviated the need of pump irrigation especially in the downstream area. Though people are trying their best to cultivate the land by pumping and conventional spate irrigation depending on the nature, a major portion of the fertile wadi bed comes under the sand dunes, and the groundwater table gradually reduces. To restore the prosperous agricultural past of the Marib area, with a financial grant from the Government of Yemen and Abu Dhabi Fund for Development, the Marib Dam and Irrigation Project was conceived in 1976 by replacing the old spate irrigation system through a modern and economic perennial irrigation system.

After a preliminary investigation and the submission of a Feasibility Study in June 1978, the concept of spate irrigation was changed in favor of total agricultural development of the area based on assured irrigation water from Wadi Abida by providing a storage dam and main line canal irrigation system as Phase I of the project. The project is under direct control of Eastern Region Agricultural Development Authority (ERADA), a wing of Ministry of Agriculture and Irrigation. Detailed designs and tender documents for the dam project were formulated in 1981.

After a tendering process followed by construction, the new Marib dam was completed in 1986. The work for main lined canal system was also completed in 1986. Concurrent with the formulation of the Marib dam project, there have been significant economic developments in the area. Moreover, the discovery of oil reserve about 60 km north-west of the project area has added to economic upsurge. In 1987, the Government decided to extend the scope of work by implementing the secondary canal network in Phase II. In September 1989, the first water conveyance test was conducted. The details of the scheme showing the location of the main dam, diversion structures A and B, and main canals A, B, BN, BB, and BS are presented in Figure 3.

Marib Dam and irrigation project, Figure 1 Location of Marib in the Republic of Yemen.

Marib Dam and irrigation project, Figure 2 Remains of the original Marib dam in the sixth century B.C.

Due to the civil unrest in the area among different tribes, the contractor was unable to complete the work. In the month of March 1990, after completion of only 6% of Phase II, the contractor started demobilization, leading to termination of the contract. Installation of precast units and

construction of different structures for secondary canalette were left incomplete, and the system was un-operational.

Condition of the irrigation system

The occurrences of high frequency of rainfall in the year of 1994 and 1996 caused a flash flood through various wadis (wide-bedded rivers) which damaged the crops, canals, and canal structures severely. The flood washed out a considerable reach of BN canal and its regulation structures away (Figure 4).

As the system was incomplete and inoperative since 1990, a large stretch of canal system and the control structures became buried under sand due to excessive sand storms and movement of the sand dunes (Figure 5).

The culverts across the main canal also became inaccessible in most cases due to the erosion of approach ramps, and local people have made crossing over the canal possible by filling it with sand.

The extent of damages witnessed in the 1996 flood was a serious concern to the country. The Government of the Republic of Yemen initiated action for the study of flood protection required for taking up appropriate measure. Accordingly, in 1998, appropriate flood protection measures were taken up for the main canal

Marib Dam and irrigation project, Figure 3 Plan of the Marib irrigation scheme, showing location of the main dam, diversion structures A and B, and main canals A, B, BN, BB, and BS.

Marib Dam and irrigation project, Figure 4 Flood damage to canal network.

system: construction of secondary canal system, repairing works of primary canals damaged during 1996 floods, and construction of feeder roads along the main canals as outstanding works of Phase II.

Study of the rehabilitation of the canal system was completed in 1999, and the construction work was completed in 2003.

Project area

The dam is constructed across the main river, Wadi Abida. The length of the reservoir is 10 km, and its area is 30.5 sq km. The downstream of river Wadi Abida after the dam is called Wadi As Sudd. After aerial survey, depending upon the land tenure, land use, fertility of land, and tribal boundary, a total command area of 7,400 ha has been selected to bring under direct irrigation from the scheme including 405 ha for canal A at the left bank of Wadi As Sudd, 3,971 ha for BS canal at the right bank of Wadi As Sudd, 3,071 ha for BN canal at the right bank of Wadi Sailah,

and 736 ha of area for BB canal between the command area of BS canal and BN canal. The major crops of the area are wheat, sorghum, lucerne, citrus, vegetables like tomato and potato, and watermelon. Only 35% of the planned command is presently being cultivated by the help of pump irrigation.

Hydrology

Though the flood of Wadi Abida is arrested by the main dam and the excess water in Wadi As Sudd is controlled by diversion structures A and B, the flood of Wadi Sailah originating from eastern hill of the project area and flowing along the left command boundary of BN canal is totally uncontrolled and beyond the managing capability of local farmers. Wadi Sailah and its tributaries drain off about 300 sq km and causes disaster in 5–10-year-frequency floods. Though the rainfall in the project area is scanty, the mean annual rainfall is 100 mm. Rain in hilly zones generates flash flood through these wadis.

The irrigation system

Main dam

The new Marib dam (Figure 6) is a zoned earth fill dam, 38 m in height and having a 780-m-long crest with central impervious core functioning as positive cutoff in the alluvial foundation and shell zones on either side. It has a storage capacity of 400 million cubic meters. Curtain grout has been provided in the abutments on both the flanks of the wadi. The reservoir area of the dam is 30.5 sq km. From the bottom sluice of Marib dam, 35 cumec water is to be released in to Wadi As Sudd to feed irrigation network for providing irrigation water to 7,400 ha of the command area.

Diversion structures

About 11 km downstream of the main dam, diversion A structure has been constructed across Wadi As Sudd to control the flow of water to feed canal A. It is a concrete “ogge” shaped spillway section with head works at its right side (Figure 7).

Marib Dam and irrigation project, Figure 5 Buried canal structure under sand dune.

Marib Dam and irrigation project, Figure 6 The new Marib Dam.

About 5 km further downstream of diversion A, diversion B structure has been constructed across Wadi As Sudd to regulate the flow requirement in feeder canal B. This is also a concrete “ogge” shaped spillway section with head works at its left side.

Main canal system

Canal A takes off from the head works of diversion A. The capacity of canal A is 840 l/s. The 4.8-km-long canal is constructed to irrigate 405 ha of command area.

One-kilometer-long canal B takes off from the head works of diversion B. The capacity of the feeder canal B is 15 cumec. At the tail end of canal B, distribution structure B is constructed to trifurcate canal B in three main canals – BS, BN, and BB canals. The structure controls and distributes water to 15.75-km-long BN canal,

Marib Dam and irrigation project, Figure 7 Diversion Structure A.

3.75-km-long BB canal, and 16.8-km-long BS canal. The distribution of water is achieved by a combination of NEYRTEC-type distributor modules (product of Alstom). Each module consists of series of slide gates, which control the flow of water. The upstream water level is kept nearly constant. Design capacity of BN canal is 6.5 cumec to irrigate 3,071 ha area. The capacity of BS canal is 7 cumec to irrigate 3,190 ha area. Capacity of BB canal is 1.5 cumec, and its command is 736 ha.

The main canal system is a completely concrete-lined canal of trapezoidal cross section (Figure 8). The steeper slope of the ground has been negotiated by providing numbers of drop structures in the main canal system. The head of the main canal system is automatically regulated by the combination of AMIL gates and CHO gates. Automatic siphon units have been introduced at the upstream of the AMIL gate to avoid any malfunction due to excess water in the main canal. From this main canal, few branch canals are also designed to supply the water at the head of the secondary canal where command area is far from the main canal.

Secondary canal system

Eighty-eight-kilometer-long secondary canal system is developed to supply water in 22 sectors – each having an area varying from 100 to 460 ha. From the secondary canalette, turnout structures are designed to serve water at tertiary channels for different blocks varying from 10 to 30 ha. After analyzing crop-water requirement, the required design discharge is derived as 2.2 l/s/ha.

To avoid the seepage loss, minimize the land acquisition, and for easy as well as rapid construction in sandy soil, three types of semicircular reinforced concrete precast units (called canalette) of standard length of 5 m and 2.5 m have been used depending upon the discharge. These precast units are placed over a combination of precast monoblock, pier, and standard saddle support over Class C concrete foundation under the ground level (Figure 9). To provide expansion, joint elastic strips have been used between the saddles and canalette, and

Marib Dam and irrigation project, Figure 8 View of main canal.

Marib Dam and irrigation project, Figure 10 Culvert across secondary canalette.

Marib Dam and irrigation project, Figure 9 View of secondary canalette.

bituminous sealant has been provided between the gaps of two canalettes. The slope of the secondary canal is fixed in such a manner that the design velocity through the canalette will be always lower than its critical velocity. The whole system is designed by an interesting computer program developed by the consultants for quick and appropriate installation. The precast units and its foundations are designed for impact and seismic effect. For all types of precast units, concrete was poured in the steel forms and simultaneously vibrated with vibration table for a period of 5–8 min. After 2 h of steam curing at a temperature of 70°C, the outer form was removed, and the inner form was removed after 3 h of additional steam curing. After removal of forms, all the precast units were placed in curing pool for 7 days.

The elevated secondary canalettes act as branch canal. At the turnout point of secondary canalette, double baffles XX2-type NEYRTEC modules (product of Alstom) of 10–60-l/s capacity have been installed for steady supply of water in tertiary channels, depending upon the size of the blocks. The discharge can be controlled by raising or lowering the steel flaps, provided in the modules. Individual fields will be irrigated through the earthen field channel taken off from the tertiary outlets. This earthen channel would be constructed by the local landowners as per their planning. Numbers of slab culvert have been provided at the existing roads to cross the secondary canalettes (Figure 10).

Road network

Side by side with the agricultural development, the project authority made an ambitious plan to connect the adjoining villages to the main city market by feeder roads to facilitate transportation of agricultural products to the cooperative market. The feeder road is of asphalt, 40-km-long and 6-m-wide asphalt feeder along the main canals, and a 70-km-long gravel-surfaced road along the secondary canalette joining the villages has been taken up (Figure 11).

Flood protection scheme

As the flash flood is the major reason for the disaster of the canal system, special care has been taken for the flood protection scheme. A 25-km-long flood protection embankment is being constructed to protect the command boundary of BN canals and the adjacent villages, which are vulnerable to flood from the flood of Wadi Sailah. The protection scheme is designed for 50-year-frequency flood of magnitude of about 700 cumec. The toe of the embankment is protected with 1-m-thick and 5-m-wide

Marib Dam and irrigation project, Figure 11 Road network.

Marib Dam and irrigation project, Figure 12 View of flood protection embankment.

wire mesh gabion boxes, and the waterside slope is protected with 50-cm-thick hand-placed stone pitching over filter. The top of the embankment is also protected with gravel pitching (Figure 12). Controlled pipe outlet structure has been provided to the riverside agricultural land through the embankment to facilitate conventional spate irrigation during rain. Remodeling of diversion A and diversion B is also being done to increase their spilling capacity.

Sand dune combating scheme

Considerable stretch of the main canal system passes through the sand dune prone areas. Excessive sand storms and movement of the dunes have affected the system badly. To combat the windblown sand affecting the function of canal system, the following treatment is being carried out (Figure 13):

- Planting of two rows of (staggered) Casuarina sapling along the canal bank in the windward side.
- Planting of single rows of Casuarina sapling along the canal bank in the leeward side.
- In the worst sand-blown areas, plantation of additional strips of vetiver grass.

Cost of the project

The cost of the Phase I work including dam and main canal system was completed in US\$ 75 million. The budgeted cost of Phase II works including production and installation of secondary canalette was US\$ 22 million. Though the production of precast canalette was over, only 6% of the secondary canalette was installed. The cost of present execution of outstanding works including repair of canal, installation of secondary canalettes and feeder roads, and flood protection scheme is US\$ 23 million.

Benefit

On completion of the project 65% additional area in the form of barren desert would be irrigated through the canal system. After recharge of the aquifer, the raised water table improved pumping. Farmers are now able to use the floodwater from the wadi in a controlled manner.

Marib Dam and irrigation project, Figure 13 Typical detail of plantation to combat sand dune.

The agricultural production will suffice internal demand and increase export possibility. The development of road network added the importance of the area and the rapid development of shops and hotels. Extensive training by the consultants was given after completion for the operation and maintenance of the project.

Challenges

Here in Marib, the relation between families and tribal groupings is complex, being influenced by blood relationship and dominated by Islamic and pre-Islamic laws and traditions. The habit to take revenge has been passed on throughout generations and still aggravates the social situation today. Till date, people prefer to obey the tribal laws rather than Government rules. At the beginning of the project, people had a hostile attitude about this Government endeavor. But after repeated campaigning about the benefit of the project, people are now in favor of the project. Repeated changes in alignment due to frequent disputes over land boundaries, demands for compensation from Phase I and for Phase II, and old unresolved tribal problems caused several isolated stoppages in the project and delayed the progress of work. Marib dam is the largest dam in Yemen with its glorious history. Completion of the Marib dam and irrigation project in the adverse climatic and social condition is a major challenge to the Government of Yemen and Abu Dhabi Fund for Development. It has created an example to the world as a “Wonder in the Desert.”

MASS CURVE AND RESERVOIR DESIGN

Hans Bergh

Department of Hydraulic Engineering, Royal Institute of Technology, Stockholm, Sweden

Description

A reservoir is essentially a lake with a dam in its outlet where the flow can be controlled. The reservoir can be either a natural lake or created by the construction of a dam in a river.

The purpose of a reservoir is to store water during periods of high flow, for example, a rainy season or a snow-melting period, and for use during periods of low flow or droughts, for example, for water supply, irrigation, hydroelectric power, or a combination thereof.

The maximum level to which the reservoir surface is allowed to rise during normal operating conditions is called *normal maximum pool level*. The lowest elevation to which the reservoir surface is allowed to be drawn during normal operating conditions is called *the minimum pool level*. The volume retained between these levels represents the water volume that can be used and is called *active (useful) storage*. The volume below the minimum pool level can normally not be used and is called *dead storage*.

The maximum amount of water that can be released from a reservoir during a dry period, *the firm (safe) yield*, can be determined a mass curve (Rippl diagram), where the accumulated natural inflow adjusted for evaporation losses is plotted as a function of time as shown in the [Figure 1](#).

Mass Curve and Reservoir Design, Figure 1 Determination of the firm yield and required storage with a mass curve.

MEMPHREMAGOG, LAKE

Armand LaRocque¹, Jean-Marie M. Dubois²

¹Department of Forestry and Environmental Management, University of New Brunswick, Fredericton, New Brunswick, Canada

²Département de Géomatique Appliquée et CARTEL, Université de Sherbrooke, Sherbrooke, QC, Canada

Location

Lake Memphremagog (Figure 1) is an international lake across the Canada–USA border (Figure 2), with about three quarters of the 102 km² lake's surface area in the region of Québec called "Estrie" or "Eastern Townships" (Canada) and the remaining part in Vermont (USA). The lake is oriented north to south, from Newport (Vermont) to Magog (Québec). It is about 43 km long and

Memphremagog, Lake, Figure 1 Aerial view of Lake Memphremagog, from the Northwest, at its outlet at Magog (coll. J.-M. M. Dubois).

1.5–5 km wide. Its shoreline measures about 120 km long. The lake is relatively deep, with a maximum water depth of 117 m, which measured just at the bottom of Mount Owl's Head. It has three distinct basins: one deep central basin, and two shallower north and south basins. It counts about 20 islands; the largest one being the Province Island, which is located on the international border. The lake watershed is less than 1,800 km², with about three quarters located in Vermont. In Vermont, three rivers (the Black, Barton, and Clyde rivers) reach the lake at its extreme south end. The outlet of the lake is the Mago River, which flows northeast and reaches the Saint-François River, at Sherbrooke. This river is an important south tributary of the St. Lawrence River.

Memphremagog, Lake, Figure 2 Map of the Lake Memphremagog basin.

Origin and evolution

The shape of Lake Memphremagog is similar to an elongated finger or to a boomerang, with two excrescences: Fitch Bay and Sargent Bay. This shape is related to an elongated basin between the Sutton Mountains, on the West, and the Upper Appalachian Plateau, which is a region of rolling hills and valleys, on the East (Dubois, 1989). It is mainly due to three major past events: the Appalachian orogen, the Quaternary glaciations, and the last ice retreat. Firstly, the lake is located in the Appalachian terrains, which are a series of mountains and highlands, stretching along the eastern portion of the North America continent. The Appalachian orogen was the result of the collision of two large supercontinents (the Laurentia and the Gondwana) and the Paleozoic closure of the Iapetus Ocean. This geologic event is characterized by uplift and folding of seafloor deposits, and by intrusion of volcanic and plutonic magmas. The configuration of Lake Memphremagog mostly follows these folded and faulted

Memphremagog, Lake, Figure 3 Seasat image of the Lake Memphremagog area, showing its main geological and glacial features (Courtesy of NASA).

strata. The northern half of the lake and the Sargent Bay occupy the bottom of a syncline, while the Fitch Bay follows the position of a thrust fault (Figure 3).

Second, the basin of Lake Memphremagog has been slightly remodeled by glaciers during the Quaternary glaciations. At that time, ice covered several times this portion of North America. During ice advances and retreats, glaciers dragged rocks and soil beneath them, which resulted to a down smoothing of the mountains along the west side and a deepening of preexisting valleys at the lake site (Sangree, 1953). Directions of ice flow follow the axis of the lake (Figure 3), supporting the hypothesis of glacial gouging of a preexisting valley. Moreover, the lake floor is also covered by more than 100 m of unconsolidated postglacial and probably preglacial sediments (Turgeon et al., 2003).

Third, the actual lake is the relic of a late-glacial ice-dammed lake. During the last deglaciation, a Laurentide ice front retreated northwestward across the region. It has blocked the normal drainage and impounded a proglacial water body in the current basin of Lake Memphremagog. Hitchcock (1895) first recognized the existence of this ice-dammed lake, and Hitchcock (1908) called it "Glacial Lake Memphremagog." More recent studies (McDonald, 1968; Stewart and MacClintock, 1969; Boissonnault and Gwyn, 1983; LaRocque et al., 2003) determined at least eight successive glaciolacustrine levels (375 m, 355–360 m, 350 m, 320–325 m, 305 m, 270–275 m, 265 m, and 235–270 m) for that lake. The lake had its maximum extent during the lowest level, known as the Sherbrooke Phase (Figure 4). It was drained westwards, via the Lac Nick spillway and the Missisquoi River, into Glacial Lake Vermont, another ice-dammed lake which occupied the basin of Lake Champlain, prior to the Champlain Sea (Parent and Occhietti, 1999). Just after the maximum extent of Glacial Lake Memphremagog, at about 12,200 years BP, the water level rapidly fell of about 40 m (Parent and Occhietti, 1999). This event marked the end of Glacial Lake Memphremagog and the beginning of the residual Lake Memphremagog. Since that time, the water level in the Lake Memphremagog basin has lowered gradually, with the gradual incision of the lake outlet. Since the end of the eighteenth century, the lake level is artificially controlled by a dam which was built on the Magog River for hydraulic power production. The current dam was built in 1920 just inside the town of Magog (Québec) for the electrical power production and maintains the lake level at an elevation of 208 m above sea level.

History

Since the first human settlements in the area after the last glaciation, native peoples always used Lake Memphremagog as a canoe route. They also sparsely occupied the lakeshore because the lake was a source of foods and drinkable water. The native past of the lake is recalled by several location names, like Indian Point, Magog, and Wigwam Point. The name of the lake itself,

Memphremagog, Lake, Figure 4 Maximum extension of Glacial Lake Memphremagog (Modified from Parent and Occhietti, 1999 and LaRocque et al., 2003).

Memphremagog, is an Abenaki word meaning “*great water plane*” (Commission de Toponymie du Québec, 1994). The first European settlements were established in the region at the end of the eighteenth century, after the American Revolution. At that time, part of the British peoples, who stayed loyal to the British Crown, left New England for Canada through the lake. These *United Empire Loyalists* settled in Newport (Vermont) in 1793 and at Gibraltar Point (which is now located in Bolton Township, Québec) in 1794. In 1797, the British Crown established for these Loyalists the two first townships in Canada (Bolton and Potton) on the west side of the lake. By mid-1800s, the region became one of the first touristic regions of Québec and the lake became a vacation resort. Tourism dramatically increased when the railroad reached both ends of the lake (Gagnon, 2003). First-class hotels were built along the lakeshore for tourist accommodation. Two steamboats (*Mountain Maid* in 1850 and *Lady of the Lake* in 1867) were used to travel from one end of the lake to the other. Since 1857, the summit of Mount Owl’s Head on the west shore is the site of initiation for the Freemasonry Golden Lodge of Stanstead. It is the only open air

lodge in North America, which is still used each summer solstice. After 1850, the development of the railroad and the forestry industry allowed the establishment of French Canadians. They were the majority in population by the beginning of the twentieth century. Presently, the area surrounding the lake is covered mostly by forest lands, except in Vermont where it is largely dominated by agricultural fields. The area has significant summer and winter recreation activities both in Vermont and in Québec.

Water quality

The Lake Memphremagog and its watershed support a diversity of plant, fish, and wildlife species habitats. However, like many other freshwater bodies, this lake is faced with accumulation of phosphorus, chlorophyll, sediments, and other pollutants, affecting water quality. This degradation is mainly shown by a premature aging of the lake, which is currently in a mesotrophic stage, especially in low depth zones. This is mainly the case at the south end of the lake, where three rivers provide the primary input of nutrients into the lake. By contrast, the central and north parts of the lake remain oligotrophic. The lake area is also

facing with invasion by nonnative species, like populations of Eurasian water milfoil and possible lake infestations by zebra mussels.

Since the 1970s, a cooperative effort between Vermont and Quebec has been made to improve this natural resource and to protect it against polluting effects of direct discharges into the lake and its tributaries. First, an international commission was initiated to manage the water level of the lake. In 1989, a working group was established to identify the principal causes of lake management problems and to take actions for preserving its environment. The commission produced a final report in 1993 and a Québec/Vermont steering committee was established to apply its recommendations. In 1994, the Lake Memphremagog Watershed Association was created to bring together citizens interested in lake and river issues in the lake basin. Since 2003, this working group is interested in all the watershed of Lake Memphremagog (Simoneau, 2004). Currently, more attention is given for addressing sources of diffuse pollution.

Myths

Several myths exist about Lake Memphremagog, among them the supposed existence of an aquatic monster, called “Memphré” (Meurger, 1982). It is considered as a 13-m inland sea serpent. This underwater lake-dwelling creature would be a cousin of the famous “Nessie,” from the Loch Ness (Scotland), and “Ogopogo,” from Lake Okanagan (Central British Columbia, Canada). The apparition of Memphré was first reported in 1816 as the native myth of the sea serpent “Anaconda,” and since then, more than 500 reports by different peoples have been recorded. However, it is still not possible to demonstrate the existence of Memphré in the lake, but the Vermont Legislature adopted an Act (number J.H.R. 19) for the protection of “Memphré.” For studying the “Memphré,” the *International Society of Dracontology* (<http://www.memphre.com>) was founded in Magog in 1986 by the “father of Memphré,” Jacques Boisvert, who died at the beginning of 2006. The mother of “Memphré” is Barbara Malloy from Newport.

MEROMICTIC LAKES

Ken J. Hall¹, Thomas G. Northcote²

¹Environmental Engineering, The University of British Columbia, Vancouver, BC, Canada

²The University of British Columbia, Summerland, BC, Canada

Classification and terminology

Lakes are classified based on the seasonal thermal conditions that determine stratification and mixing processes. These conditions are affected by changes in lake morphometry (depth, surface area), drainage basin morphometry (area, topography, climate), and dissolved and suspended solids in their waters (vertically, seasonally, annually). Lakes where water circulates throughout the entire water column are called *holomictic* lakes and are by far the most common. Usually, this occurs at least twice annually in temperate regions, with such lakes being called *dimictic*. Lakes that do not undergo complete circulation are referred to as *meromictic* lakes and occur when salinity or turbidity gradients set up concentration profiles

with enough density difference to bring about stability of their lower layers (Hutchinson, 1957; Wetzel, 2001). This stability isolates the bottom water from the surface water, and terminology has been developed to describe these zones within these lakes (Findenegg, 1937). The upper zone that undergoes periodic (often twice a year) circulation is called the *mixolimnion* and the lower zone is called the *monimolimnion*. These zones are separated by a very steep but usually relatively thin chemical and hence density gradient called a *chemocline*.

Meromictic lakes can be classified based on the conditions and processes that bring the saline and freshwaters together in the same basin to set up sharp density stratification conditions. *Ectogenic* meromixis often occurs in coastal areas where seawater due to a storm event or extreme tidal activity intrudes onto a freshwater low salinity/density layer. Seawater in fiord areas can also be trapped as glaciers melt and the land surface rebounds with subsequent freshwater runoff setting up the conditions for meromixis. Examples of this kind of meromixis include Nitinat and Sakinaw Lakes in British Columbia (Northcote and Johnson, 1964; Northcote et al., 1964.) and Lake Tokke in Norway (Strøm, 1955). *Crenogenic* meromixis occurs when saline springs discharge dense water onto a freshwater lake depression setting up density stabilizing conditions. Examples of crenogenic meromictic lakes are Ulmener Maar in Germany (Stewart and Hollan, 1975) and Lake Sinmiyo in Japan (Yoshimura, 1937). *Biogenic* meromixis results from an accumulation of higher dissolved solids as a result of decomposition processes in the bottom of the lake that gradually stabilizes the bottom layer and prevents complete circulation. Examples of biogenic meromictic lakes include Lake Mary, Wisconsin (Weimer and Lee, 1973), as well as Wörthersee and Millstättersee in Austria (Hutchinson, 1957). Mahoney Lake in British Columbia could also be classified as a partially biogenic meromictic lake, but surface runoff from saline rich geological formations in the watershed with no lake outflow and evaporative concentration also have helped to establish meromixis (Northcote and Hall, 1983). Yellow Lake, also in British Columbia, can also be classified as biogenic, but the lake lies in a remnant glacial meltwater channel and its morphometric features (deep, narrow, and protected from high winds) have helped to set up meromixis in this lake (Northcote and Halsey, 1969).

No classification system for meromixis is perfect. More recently, Walker and Likens (1975) proposed a modified classification that only has two classes of meromixis, namely ectogenic and endogenic, and then segregates lakes under these classes into several types based on the physical-chemical process that helps to create the stability. Anderson et al. (1985) used this classification system for a comprehensive list of North American meromictic lakes with varved sediments.

Some lakes may be classified as *partially meromictic*. This can happen where there are two basins in the lake, and usually the deeper basin sets up meromixis such

as what occurs in Baptista and Amisk Lakes in Alberta (Kira, 1995). Partial meromixis may also occur seasonally where the influx of freshwater in the spring due to snow-melt causes a density difference that isolates the lower water for part of the season until evaporation or wind mixing breaks down the density stratification.

Geographic distribution

We attempted a compilation of a list providing reference to most of the meromictic lakes that have been identified and/or studied in the world. These lakes have been segregated globally into nine regions (Figure 1). The comprehensive listing of North American lakes with varved sediments provided by Anderson et al. (1985) identifies 88 meromictic lakes, and the reader is referred to this reference and its literature citations. Our geographic summary of meromictic lakes indicates that most identified meromictic lakes occur in North America and Europe. The meromictic lakes in Africa are largely deep ones localized in the rift valleys or in remains of volcanic cones. Although there are numerous saline lakes in Australia, the arid conditions on that continent generally prevents establishment of meromixis. Only four meromictic lakes have been reported on that continent with three of these located in Tasmania (Bayly and Williams, 1973; Croome and Tyler, 1984). Polar meromictic lakes are likely formed by the freeze-out of salts helping to establish a fresher surface layer. No literature could be found on meromictic lakes in South America. The 17 chapters on limnology in Brazil (Tundisi et al., 1995) make no mention of meromixis there, especially that by Henry (1995) covering the thermal structure of 16 widespread lakes and reservoirs in that large part of South America, nor in over 100 lakes in the Rio Doce valley, Brazil (Tundisi and Saijo, 1997). One might expect to find a few meromictic lakes in parts of Chile and Argentina.

Meromixis and thermal stratification

The saline stability of meromictic lakes leads to some interesting thermal conditions in their vertical profiles that can have a significant influence on physical and biological processes. The bottom monimolimnion of many meromictic lakes is relatively warm and this temperature can be very stable over the seasons and over many years. The bottom waters of Mahoney Lake in British Columbia, Canada, have been constantly between 12°C and 15°C for the past 30 years. Solar energy can be trapped under less saline surface water, and temperatures in excess of 50°C have been recorded in the chemocline of shallow Hot Lake in Washington (Anderson, 1958). Recently, Northcote and Hall (2000) introduced the term “bimeromixis” when periodic vernal influx of freshwater caused the formation of a secondary chemocline in the mixolimnion with temperatures up to 30°C in May at 2–4 m in Mahoney Lake. In this area of secondary stability, heterotrophic activity was stimulated with a high uptake of radioactive solutes (Hall and Northcote, 1990). This bimeromixis also intensified primary production processes with dissolved

Meromictic Lakes, Figure 1 Location and reference to identified meromictic lakes of the world (the numbers in the boxes of each region are keyed to the alphabetic reference list which identifies the specific lake and its location in *bold* letters; the number in brackets gives the total number of meromictic lakes identified for that region; the filled circles delineate 66°N latitude to show the region of the Arctic).

oxygen concentrations reaching 25–30 mg/l (up to 300% supersaturation) during the summer period (Hall and Northcote, 2002). This biological stimulation is most likely attributable to an influx of nutrients from spring run-off and the flooding of the littoral zone by a higher lake level, as well as trapping and recycling of nutrients associated with detrital material that collects at this stable boundary.

Meromictic effects on lake geochemistry and microbial processes

The long-term stratification of meromictic lakes with isolation of monimolimnion waters from circulation sets up redox conditions that influence decomposition and phototrophic carbon fixation processes throughout the water column. The monimolimnion becomes highly anoxic in meromictic lakes, and high concentrations of hydrogen sulfide can accumulate when sulfate-reducing anaerobic bacteria (*Desulfovibrio*, *Desulfotomaculum*) use sulfate as an electron acceptor during heterotrophic decomposition of organic matter (Wetzel, 2001; Sorokin, 1970). The chemocline with its steep chemical gradient creates a sharp redox gradient where oxygen concentrations can rapidly decrease to zero and several 100 mg/l

of hydrogen sulfide can occur over a depth interval of 20 cm (Overmann et al., 1991). If light energy penetrates to the chemocline, in the presence of the hydrogen sulfide which serves as an electron donor, dense plates of phototrophic purple sulfur bacteria can develop (Northcote and Hall, 1983; Overmann et al., 1991). This very small layer can contribute to a significant percentage (17–66%) of the autotrophic carbon fixation in the water column (Hall and Northcote, 1990). Green phototrophic bacteria (*Chlorobacteriaceae*) can also develop at these stratified boundaries, but they are not usually as dense as the purple sulfur bacteria (*Thiorhodaceae*) (Wetzel, 2001).

Observations of sulfur bacteria in the guts of copepods (*Diaptomus connexus*) and subsequent studies of stable sulfur isotopes and ¹⁴C food chain studies demonstrated that these aerobic organisms could obtain energy fixed in the anoxic environment by the anaerobic purple sulfur bacteria as the copepods made excursions into the chemocline to graze on the bacteria (Overmann et al., 1999a). Water level changes can make the stability of the chemocline vulnerable and along with the development of buoyancy by the purple sulfur bacteria can disperse bacterial clumps into the mixolimnion, grazed upon by ciliates and invertebrates (Overmann et al., 1999b).

When this occurs, the shoreline of lakes is often coated with a film of purple sulfur bacteria. For more detailed studies on the seasonal dynamics and long-term changes in meromictic lakes, the reader is referred to the extensive literature published on Längsee (Austria), Big Soda Lake (Nevada), Mono Lake (California), and Mahoney Lake (British Columbia).

Sediments in meromictic lakes

The anoxic conditions in the monimolimnion exclude benthic invertebrates from much of the sediment. This prevents sediment bioturbation or disturbance, and often the seasonal production and precipitation processes create distinct annual layers, called varves, which are easily visible in a sediment core (Lowe et al., 1997). The sediment cores allow detailed sedimentological studies to be conducted which can provide long-term information on development of salinity in the lake. Historic lake salinity changes in Mahoney Lake have been inferred from the identification of diatom and chironomid remains in the sediments (Heinrichs et al., 1997). Pigment preservation in anoxic sediments helps to determine how long and when purple sulfur bacteria have been present in a lake. In the example of Mahoney Lake, the sediment profile of the carotenoid, okenone, which is the pink accessory pigment of *Amoebobacter purpureus*, indicates that the purple sulfur bacteria have been in the lake for approximately 9,000 years and that meromixis may have existed in this lake for a similar period (Overmann et al., 1993). Algal pigments can help determine how the phytoplankton community has changed historically and how important it is in lake primary production compared to that of phototrophic purple sulfur bacteria.

Meromixis in the past, present, and future

Information on climate change since last glaciation can also be studied by investigating the extent of chemical precipitation events and the chemistry of the elements in the core, and the long-term presence or changes in the degree as well as type of meromixis (Lowe et al., 1997; Hall and Northcote, 2000).

Coastal and near-coastal lakes may trap seawater for short or long periods of time depending on the multiple effects of deglacial isostatic rebound and higher sea levels. For example, Powell Lake lying some 60 m above present sea level contains in its bottom waters a salinity of 18‰ which entered the lake basin some 13,000 years ago when coastal waters were heavily diluted by massive meltwater dilution resulting from deglaciation (Williams et al., 1961). In contrast, present-day Nitinat Lake on the west coast of Vancouver Island is partially meromictic, containing at depths below 3 m saline water close to that of the coastal Pacific Ocean into which it drains from its short (<2-km) outlet river. At high tide levels combined with strong onshore winds, nearby coastal seawater may enter the lake basin setting up strong meromictic conditions (Northcote et al., 1964). Just over 100 km northeast of Nitinat Lake lies the coastal mainland lake Sakinaw,

some 3 m above present sea level, and offering a clear example of present-day ectogenic meromixis (Northcote and Johnson, 1964). Sakinaw Lake is two-basined, its main portion having a maximum depth of 140 m and its smaller northeastern basin a 40-m maximum depth, and that of the nearby Ruby Lake 100 m. Only the lower basin of Sakinaw Lake is meromictic now, with its upper basin and that of Ruby Lake being holomictic. Probably in the recent geological past all three basins of the Sakinaw–Ruby chain were filled with coastal seawater, a feature that should be checked out by deepwater coring.

Another presently meromictic lake (Mahoney) lies in South Central British Columbia (Northcote and Halsey, 1969) where a 5.45-m-long sediment core gave its age as over 11,000 year BP (Lowe et al., 1997) and from which Holocene fluctuations in its meromixis, water level, and depth, along with local climatic changes, could be inferred. Meromixis developed in the lake about 9,000 year BP and has been episodically meromictic for about half of the time since then when Holocene temperatures and aridity were at a maximum in western Canada and the northwestern United States. Outstanding features of the Mahoney Lake record are the rapidity and high frequency of inferred climatic changes (Lowe et al., 1997) along with longer periods of relative stability, following patterns called climatic “flickering” – short-term oscillations between distinct climatic states (Lehman, 1993; Taylor et al., 1993). The prediction and assessment of future global environmental change on lake morphometry, inflow discharge, ice-free period, and water temperature have been reviewed for British Columbia in general and South Central B.C. in particular (Northcote, 1992).

MICROORGANISMS IN LAKES AND RESERVOIRS

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

Although invisible to the naked eye, bacteria in the form of microorganisms are present in all water bodies, particularly in the sediments of lakes, reservoirs, and rivers. These organisms have a key role in the nitrogen cycle and are involved in biological processes. Bacteria play the central role in natural self-purification by decomposing organic matter into its inorganic components which are then recycled. *Pathogenic organisms, bacteria, and viruses* are of particular concern in lakes

and reservoirs used as a source of potable supply or for bathing. In the case of potable supplies, modern water treatment processes, including disinfection, ensure that sources are well protected and that any pathogens present are removed by filtration or killed.

Cyanobacteria are an important group of plants often appearing a dominant part of the phytoplankton of lakes and reservoirs. They tend to form a dense surface bloom rising to the surface and drift to form massive suspensions which may be 1 m in depth. They are a major health concern because some species produce highly toxic secretions which cause skin irritation and serious stomach upset if consumed. The main genera in lakes and reservoirs are *Microcystis*, *Anabaena*, *Nostoc*, *Aphanizomenon*, and *Rivularia*.

The following is a list of some of the important microorganisms found in water, including lakes and reservoirs.

The following microorganisms are found in water:

Aelosoma A member of the family Aelosomatidae of the oligochaete worms. Found in aquatic habitats.

Amoeba A protozoan of the class Rhizopoda, which moves by the formation of temporary protrusions (pseudopodia).

Arcella A shelled rhizopod protozoan.

Aspidisca A hypotrichous ciliate found in activated sludge and indicative of good conditions.

Ascaris A parasitic nematode worm of humans (human roundworm), the eggs of which can be disseminated by the way of sewage effluents.

Asellus aquaticus (the water hog louse) An isopod crustacean found in the zone of recovery from organic pollution in a receiving water and therefore a useful indicator organism.

Baetis rhodani A species of mayfly (Ephemeroptera) present in rivers and lakes and tolerant of reduced dissolved oxygen levels in contrast to many other species of mayflies, which are intolerant of such conditions. Consequently, often present under mildly organically polluted conditions.

Beggiatoa A filamentous autotrophic bacterium capable of oxidizing sulfur compounds to elemental sulfur according to the equation:

Bodo A nonpigmented flagellate protozoan usually indicative of unsatisfactory conditions.

Caenis A genus of mayfly which lives on a muddy substratum.

Callitriche An aquatic macrophyte, commonly known as starwort.

Campylobacter First recognized as a source of self-limiting diarrheal disease in the early 1970s and later shown to be the commonest reported cause of acute diarrheal illness (in the UK).

Carchesium A colonial attached peritrichous ciliate.

Chlamydomonas A green flagellate found in nutrient-rich water.

Cladophora A filamentous green alga found commonly in water. It may cause a nuisance by producing excessive growths in nutrient-enriched water or in the final recovery zone in organically polluted receiving water. It is then known as "blanket weed."

Clostridium A genus of spore-forming anaerobic bacteria. *Clostridium perfringens* can form resistant spores which survive in water much longer than other fecal indicators. Its presence implies remote or intermittent fecal pollution. Some species of *Clostridium* can reduce sulfate to sulfide.

Colpidium A ciliate protozoan found in activated sludge.

Cryptosporidium A protozoan parasite found in humans, other mammals, birds, and reptiles. *Cryptosporidium parvum* (*C. parvum*) is a species of *Cryptosporidium* believed to be capable of causing disease in humans and livestock.

Cyclops A copepod crustacean, common in zooplankton.

Cysticercosis The bovine effect of infection by *Taenia*.

Cysticercus bovis A parasitic beef tapeworm *Taenia saginata*.

Daphnia A genus of small crustacean of the suborder Cladocera, commonly known as "water fleas." Common member of the zooplankton of lakes and reservoirs and sometimes used as test animals in toxicity tests.

Dendrocoelum lacteum A flatworm (Turbellaria) of the phylum Platyhelminthes. Used as an indicator organism.

Desulfovibrio desulfuricans A bacterium which reduces sulfate to hydrogen sulfide, thus:

Entamoeba histolytica A parasitic ameboid protozoan which causes dysentery in humans and is spread by the contact with polluted water.

Enterobius A nematode worm, parasitic in humans, the eggs of which can be found in polluted estuaries.

Enteromorpha A tubular thaloid green algae related to sea lettuce *Ulva*. Found in brackish and polluted water and especially abundant in polluted estuaries.

Enterovirus A subgroup (genus) of the Picornaviridae family of viruses. Over 70 different types have been isolated from humans. Their normal site of infection is the intestinal tract, but other organs may become involved. Diseases caused range from the trivial to the fatal, including infectious hepatitis, poliomyelitis, and meningitis.

Epistylis A colonial peritrichous ciliate commonly occurring in water treatment works.

Eristalis tenax A dipterous fly with a bee-like appearance, the larva of which (known as the rat-tailed maggot) is aquatic and can, by breathing atmospheric air through a telescopic tail, exist in most organically polluted water and sludge when these are not too deep. Its presence is indicative of organic pollution.

Erpobdella A genus of freshwater leeches, commonly found in streams and lakes, which are useful indicator organisms.

- Escherichia coli* A bacterium living in the alimentary tract of humans and other mammals. As it is passed out with feces in large numbers, its presence in water is indicative of fecal contamination and the possible presence of pathogenic organisms of enteric origin; it is not itself normally pathogenic. Also known as *E. coli*, *Esch. coli*, or *Bact. coli*.
- Fusarium aquaeductum* A common biological-filter fungus having sickle-shaped spores and often having pink coloration.
- Geotrichum* A fungus commonly occurring on biological filters.
- Giardia intestinalis* (*Giardia lamblia*) is a protozoan parasite capable of infecting humans and domestic animals. It causes acute diarrheal illness.
- Glossiphonia* A genus of leeches in freshwater lakes and streams, useful as indicator organisms.
- Gammarus pulex* A freshwater shrimp which may be common in lakes and streams and is a useful indicator organism.
- Helobdella stagnalis* A species of leech, useful as an indicator organism.
- Hydrobaenus* A genus of chironomid midge, an active grazer in some biological filters. Also termed "*Spaniotoma*."
- Hydropsyche* A genus of Trichoptera or caddis flies. In their larval stages, they do not build cases like most caddis but catch their food in nets which they spin in flowing water. Useful indicator organisms.
- Hypogastrura viatica* A species of the primitive insect order Colembola, characterized by having a simple life cycle and by not having wings. A common member of the grazing fauna of many biological filters. Also termed "*Achorutes subviaticus*."
- Legionella* Organisms of the genus *Legionella* are classified as Gram-negative bacteria, of which there are at least 30 species, over half of which have been implicated in human disease. *L. pneumophila* is the causative agent of Legionnaires' disease, an acute pneumonic infection of the lungs, and greater than 85% of cases are caused by *L. pneumophila* serogroup 1.
- Leptomitus lacteus* A nonseptate aquatic fungus found in certain organically enriched water.
- Leptospira icterohemorrhagiae* A pathogenic spirochete which may invade the blood, causing leptospiral jaundice (Weil's disease), transmitted by sewer rats and their urine.
- Leptothrix* A filamentous genus of the iron bacteria. Chlamydoacteriaceae, found in organically polluted water.
- Leuctra* A genus of Plecoptera (stone flies) having aquatic nymphs in flowing water: indicative of well-aerated water.
- Limnaea* A genus of freshwater snail commonly found in fresh water and tolerant of a wide range of conditions.
- Lumbricillus* or *Pachydrilus* A genus of the family Enchytraeidae. Small worms of pale color which are common grazers in biological filters.
- Lumbricus* A genus of worm of the family Lumbricidae which includes the common earthworm.
- Litonotus* or *Lionotus* A genus of free-swimming ciliate protozoa.
- Nitrobacter* A bacterium which converts nitrite to nitrate.
- Nitrosomonas* A bacterium capable of oxidizing ammonia to nitrite.
- Nitzschia palea* A common species of diatom of value as an indicator organism of organic pollution.
- Opercularia* A genus of colonial peritrichous ciliate protozoan common in activated sludge and used as an indicator of its condition.
- Pachydrilus* or *Lumbriculus* Worms of the family Enchytraeidae, commonly found as a grazer in biological filters.
- Paramecium* A genus of free-swimming ciliate protozoa and a useful indicator organism.
- Phormidium* A blue-green algae, the filaments of which intertwine to form a sheet. Commonly found on the surface of biological filters where it may cause ponding.
- Psychoda* A genus of small moth-like flies, the larvae of which are "grazers" in biological filters.
- Potamogeton* Pondweed, which is an aquatic macrophyte with many species growing in ponds and rivers.
- Salmonella* A group of enteropathogenic bacteria responsible for typhoid fevers and food poisoning. Common in polluted water.
- Sphaerotilus* A filamentous bacterium of the order Chlamydoacteriaceae, which may form plumose growths in polluted water known as "sewage fungus."
- Streptococcus fecalis* A bacterial indicator of fecal contamination of water.
- Silvicola fenestralis* A dipterous fly whose larvae are common grazers in biological filters. The adults may cause a nuisance when they leave the filters. Formerly *Anisopus fenestralis*.
- Taenia* A genus of parasitic tapeworm of the class Cestoda, the eggs of which are dispersed through polluted water.
- Tanytus* A genus of chironomid fly, the larvae of which are aquatic.
- Thiobacillus thiooxidans* A sulfur-oxidizing bacterium which, when present in sewage, converts sulfur into sulfuric acid (which, in turn, attacks concrete) according to the equation:
- $$2S + 3O_2 + 2H_2O \xrightarrow[\text{thiooxidans}]{\text{Thiobacillus}} 2H_2SO_4$$
- The bacterium grows best in a strongly acid medium (pH 2.0–6.0) and can also oxidize thiosulfate to sulfate, thus:
- $$Na_2S_2O_3 + 2O_2 + H_2O \xrightarrow[\text{thiooxidans}]{\text{Thiobacillus}} Na_2SO_4 + H_2SO_4$$
- Ulothrix* A filamentous green algae, common in fresh water and on the surface of biological filters.
- Vaucheria* A filamentous green algae, in lakes and streams.

Vorticella A genus of peritrichous ciliate, common in activated sludge.

Zoogloea ramigera A bacterium which grows embedded in a common gelatinous matrix, forming a bacterial slime. A member of the family Pseudomonadaceae.

MIXING IN LAKES

Lake water exchange

Definition

Mixing in lakes. The exchange in space and time of lake waters containing different concentrations of matter, promoting the reduction of such differences. A wide range of processes occurs in lakes that induce mixing depending on, for example, wind, waves, heat transfer, and in- and outflows to the lake.

Introduction

Mixing is related to the transport of matter in a fluid (here, the water in a lake), where the matter may be dissolved in the fluid or in particulate form. In the general case, mixing may also occur in connection with the transport of momentum and energy, which for the latter quantity includes heat transport. Mixing implies that the transport reduces or eliminates differences in concentration of the matter in space and time, as fluid elements with different content of matter (concentration) intermingle, causing decreased concentration gradients in the water

body. This decrease in concentration gradients leads to a homogenization of the water body and the evolution toward an equilibrium state, if the forcing conditions are steady.

At the microscale (see Imboden (2004) for a discussion on scales and the motion of lake waters), transport and mixing of matter occur either through advection or diffusion (Fischer et al., 1979). Advection is the transport with the mean flow, whereas diffusion takes place when fluid elements (at the molecular or turbulent scale) are exchanged at no net flow, but with net transfer of matter. At the macroscale, a wide range of processes acts to initiate transport and mixing, for example, heat transfer at the surface or across the lake bottom, in- and outflow to the lake, wind-induced mean currents and waves, and *seiching* (see Imberger and Hamblin, 1982). At the same time, stratification may prevent water exchange since density differences act to dampen turbulence and modify the mean circulation. Most flows in nature are turbulent, although in a lake laminar conditions may prevail leading to mixing primarily at the molecular scale (e.g., ice-covered lakes).

Basic mechanisms for mixing

For turbulent flows, the local velocity at a point in a certain coordinate direction (e.g., x -direction) is typically expressed as $u = \bar{u} + u'$, where $\bar{u}$ is the mean velocity (overbar denotes averaging at a proper time scale) and u' is the turbulent fluctuation (varies in time, but has a zero time-mean value). The local concentration is described in a similar way $c = \bar{c} + c'$, where $\bar{c}$ is the mean concentration (in mass of material per unit water volume) and c' is the turbulent fluctuation. Transport due to advection may be expressed as $m_A = \bar{u} \cdot \bar{c}$, where m_A is the mass transport per unit time and area. This transport refers to a particular coordinate direction, and for the general case a transport vector in three dimensions is obtained. The transport due to diffusion for turbulent flows is obtained as $m_D = \overline{u' \cdot c'}$, where m_D is the mass transport per unit time and area. In computational approaches, m_D is often modeled using Fick's law (Fick, 1855) with the diffusive transport assumed proportional to the concentration gradient according to $m_D = \overline{u' \cdot c'} = -D_x \cdot \partial \bar{c} / \partial x$, where D_x is a turbulent diffusion coefficient. Fick's law was originally formulated for molecular diffusion, which is the prevailing mechanism for mixing under laminar conditions. The coefficient is a material property for molecular diffusion that depends on the matter in the water (e.g., salt, heat), whereas it is a function of the flow for turbulent diffusion. In the latter case the diffusion coefficient may vary substantially in space and time, making it more difficult to determine proper values than for laminar conditions. *Field measurements* are often required to obtain reliable coefficient values.

Changes in the local concentration, which reflects the mixing, occurs because of gradients in the advective and diffusive transport. Such gradients could be present in all

coordinate directions (x , y , and z) leading to the three-dimensional advection-diffusion (AD) equation,

$$\begin{aligned} \frac{\partial c}{\partial t} + \frac{\partial}{\partial x}(\bar{u} \cdot \bar{c}) + \frac{\partial}{\partial y}(\bar{v} \cdot \bar{c}) + \frac{\partial}{\partial z}(\bar{w} \cdot \bar{c}) \\ = \frac{\partial}{\partial x} \left(D_x \cdot \frac{\partial \bar{c}}{\partial x} \right) + \frac{\partial}{\partial y} \left(D_y \cdot \frac{\partial \bar{c}}{\partial y} \right) + \frac{\partial}{\partial z} \left(D_z \cdot \frac{\partial \bar{c}}{\partial z} \right) \end{aligned}$$

where t is time and $\bar{u}$, $\bar{v}$, and $\bar{w}$ are the mean velocities in the x -, y -, and z -direction, respectively. The equation above results from a mass balance for a small rectangular element where changes in the in- and outflow over the boundaries cause a change in the mass (concentration) in the element. Changes due to gradients in the advective transport are on the left-hand side and in the diffusive transport on the right-hand side of the equation. In the general case the diffusion coefficient is different in respective coordinate direction, but often in engineering studies, it is regarded as a constant in the area of interest. Solving the AD equation typically involves numerical techniques since the initial, boundary, and forcing conditions are complex for conditions in nature. Also, the mean circulation and turbulence properties have to be obtained from a flow model before the AD equation can be solved.

Mixing processes in lakes

On the macroscale it is possible to identify a number of distinct processes that cause mixing in a lake by inducing circulation and generating turbulence. Simultaneously, density differences due to temperature or salinity often promotes *stratification*, which restricts the flow development and turbulence generation. A stable density gradient counteracts vertical movement induced by the turbulence, thus having a dampening effect on the motion that reduces vertical mixing. Vertical *stratification* often develops in lakes because of low velocity, long residence times, and deeper bottom water (Imboden and Wüest, 1995), which are all factors that tend to reduce mixing. A common type of *stratification* is a two-layer system, where a surface layer (epilimnion) with a lower density develops on top of a bottom layer (hypolimnion) with higher density separated by a relatively thin density interface (i.e., thermocline, if the density difference is due to temperature). Such a system may be found in deep lakes in the temperate region during the summer. Furthermore, density differences may drive horizontal exchange of water and contribute to the mixing (Turner, 1973). The most prominent processes that affect mixing in a lake, to be briefly discussed in the following, are wind-induced mean circulation, wind-generated waves, river in- and outflow, heat transfer at the lake surface and bottom, boundary flows, *seiche*, and *internal wave* motion.

When a wind blows over a lake water surface, the shear stress generated at the air-water interface induces a mean drift in the direction of the wind that may set up a circulation in the lake. The transfer of energy from the wind to the lake surface depends on the air and water

densities, the wind speed, and the roughness conditions of the surface (including the presence of surface waves). As a rule-of-thumb, the wind-induced surface current is on the order of 3–4% of the wind speed at 10 m above the surface. For continuity reasons, in a restricted water body such as a lake, if a surface current develops, it has to be balanced by a return current along the bottom or above the density interface, if a two-layer *stratification* is present. Measured vertical velocity distributions from laboratory experiments in channels show that about 1/3 of the upper part of the water column has a current in the direction of the wind, whereas the lower 2/3 experiences a return flow. Wind-induced mean currents and associated turbulence are often the most prominent processes for mixing at the scale of the lake. A secondary flow induced by the wind is the so-called Langmuir circulation (Langmuir, 1938). This circulation, taking place as counter-rotating vortices, may be visualized as streaks on the water surface parallel to the wind direction where floating objects often gather (Leibovich, 1983). A wind speed in excess of 3 m/s is required for the Langmuir cells to form, and the spacing between the streaks depends on the wind speed in an approximately linear fashion.

The wind does not only cause a mean surface current, but waves occur as well that grow in height and period in the direction of the wind. Since the length over which the waves are generated (i.e., fetch) typically is shorter in a lake than in the sea, the waves are correspondingly smaller. Thus, in a small lake the effects of the waves on the lake might be small and limited to the area near the shore. Also, since the waves are typically generated in shallow water, the frictional losses are larger in a lake compared to the sea, acting to reduce wave growth. The waves are primarily causing three types of flow of importance for the mixing in a lake: (1) oscillatory currents at the bottom, (2) turbulence in connection with wave breaking, and (3) mean currents, primarily in the zone of breaking waves (surf zone). When waves are not breaking, they are often assumed to produce negligible net transport of water, and the motion under the waves is taken to be purely oscillatory (linear wave theory, see Dean and Dalrymple, 1984). However, at the bed the frictional losses associated with the wave motion generates turbulence that may cause mixing, and since the boundary layer is considerably thinner under an oscillatory flow compared to a uniform flow, the shear stresses and turbulence generated are larger under the former type of flow. Resuspension of material deposited on the lake bottom is often initiated by the wave motion at the bed.

Waves break when they become too steep, expressed through the wave height/wavelength ratio, or when the wave height/water depth ratio exceeds some critical value (on the order 1). The breaking is associated with marked turbulence generation that causes strong mixing. Homogenization of the surface layer in a stratified lake is promoted by wave breaking due to excessive steepening, whereas depth-limited breaking in shallow water

mobilizes bed material and initiates strong vertical and horizontal exchange. Wave breaking in shallow water also generates mean currents as the wave momentum flux decreases with the wave height reduction. The mean currents cause frictional forces that balance this decrease in momentum flux. The most pronounced current occurs if the waves break at an angle to the shoreline, creating what is known as a longshore current. A mean cross-shore current also develops (perpendicular to the shoreline), as water transported onshore in the upper part of the water column is returned along the bottom (often denoted undertow). The cross-shore current is typically considerably weaker than the longshore current, and thus of less importance for the transport and mixing. The nonlinearity of the waves, especially in shallow water before breaking, gives rise to a net drift of water in the wave direction that will induce a mean current. This current is often referred to as the Stokes drift. In a limited water body, a return flow develops that balances the Stokes drift.

Water entering or exiting a lake through a river or a similar water course also induces movement and mixing in the lake, although in general at the local scale. The relative importance of such discharges for the mixing can be assessed from the lake residence time, which is the time needed to replace the entire lake water volume by the inflow. The river water is often discharged to the lake in a jet-like manner where strong mixing takes place at the jet boundaries, entraining lake water and mixing it with the river water. This entrainment sets up a circulation in the lake extending to a region that depends on the lake geometry and the river discharge properties. At some distance from the point of discharge, the river water will become completely mixed with the lake water, losing all of its initial characteristics. This distance may extend many initial river widths. Water exiting a lake also initiates a mean flow in the lake. However, this flow typically affects a smaller region as the acceleration of the water toward the exit occurs with less energy dissipation and turbulence. In- or outflow through the ground water and inflow due to precipitation could also be important for lake mixing under certain conditions. If the water entering the lake has a different temperature or salinity, density differences may affect the discharge. Different types of man-made discharges, such as flows from sewage or cooling water outfalls, also contribute to the mixing locally.

Heat transfer at the water surface, and to a lesser degree at the bottom, causes temperature gradients in the lake, with associated differences in density, that induce mean currents. This mechanism for transport and mixing is of great significance, especially in the temperate areas where the annual cycle of lakes is a direct result of the varying heat transfer at the water surface during a year. Whether a lake will receive a net gain or loss of heat depends on the heat balance at the surface, where the most important components are incoming short- and long-wave radiation, reflected short- and long-wave radiation, emitted long-wave radiation from the water, free and forced convection (e.g.,

evaporation/condensation), and conduction. A heating up of the surface water implies a lowering of the water density and the development of a stable *stratification* (deeper water is colder and has larger density) that often leads to two-layer *stratification* in deeper lakes. This situation prevails during the summer. If the surface water is cooled down, the density increases and unstable conditions may develop where the density of the surface water is greater than the density of the underlying water. In this case, a downward flow is initiated with strong mixing as a result on a scale of the entire lake. When a lake is ice-covered, the heat exchange at the surface is negligible and the heat transfer at the bottom could become important for causing density-driven flows and mixing.

Flow over a boundary, such as the lake bottom, gives rise to shear stresses and associated turbulence generation. A more uneven, or rougher, bottom provides more resistance to the flow, enhancing turbulence generation, which may locally, close to the boundary, induce mixing. Thus, in a lake with highly variable bottom topography, local mixing near the bottom can be significant. Furthermore, if the bottom features are sufficiently large, zones of separation will develop downstream the feature with additional turbulence generation and recirculation. In such recirculation zones, local areas may arise where the mixing is smaller and material is deposited. A hole or trench in the lake bottom often causes the accumulation of fine material with possible local problems for the water quality.

Water blowing over the lake surface not only generates a mean current, but water is also pushed in the wind direction causing a tilt in the water surface over the lake, known as wind setup, with the maximum rise at the most downwind point. The size of the wind setup is primarily a function of the wind speed, the lake water depth, and the length over which the wind is blowing. In some lakes, if the wind ceases to blow after building up a marked setup, the water surface gradient induces a strong return flow that may create a setup at the opposite lake side, overshooting the mean water level. This in turn produces a flow back toward the other lake side, and an oscillatory behavior occurs that is known as a *seiche*. The *seiching* causes a mean circulation that transports and mixes the lake water. If the lake is stratified, a tilt in the water surface will produce a corresponding displacement in the density interface that is significantly larger since it is inversely proportional to the density difference between the surface and the bottom layer. The circulation in the surface layer will also induce water movement in the bottom layer through the shear generated along the density interface, but this movement is small and typically negligible.

Under certain conditions, disturbances from the surface layer can initiate waves in the density interface similar to the waves generated by the wind on the lake surface. These waves, known as internal waves, propagate along the interface, causing water movement, but typically not implying prominent mixing. However, if the internal waves become too steep, they may break and under such circumstances mixing becomes strong.

Definition

This essay describes the water quality related impacts of nutrients, organic carbon, pathogen, and phytoplankton dynamics, in an intensively studied source water reservoir used for the production of potable water.

Water quality

Water quality in reservoirs supplying water treatment plants is determined by the interaction of the physical, chemical, and biological processes that occur in the

catchment and within the reservoir. Storage of water within reservoirs provides security in terms of water quantity, but also gives the opportunity for both beneficial and undesirable changes in water quality to occur. Good reservoir management can optimize the beneficial changes and mitigate risks to water quality. There is often distinct seasonality in streamflow and transient events, such as rain event inflows, that are important for many reservoirs that supply water for potable consumption. Threats to water quality may be esthetic in nature, or may pose a serious risk to human health. Contamination of reservoirs may result from the growth of toxic cyanobacteria or the transport of pathogenic organisms from the catchment (see below). These threats to water quality may be generated over different time scales. Threats associated with rain events may occur at hourly to daily timescales, whereas changes to phytoplankton communities may take longer to manifest. Another risk factor is contamination by anthropogenic toxins (pesticides, endocrine disruptors, petroleum); these factors are either accidental and essentially stochastic, or chronic system properties that are not considered here. Other threats to water quality may be both chronic and transient. The concentration of natural organic matter in a reservoir fluctuates relatively slowly, but during periods of high streamflow, changes in its concentration and character may occur, and warrant management of the reservoir offtake. Here we demonstrate, using Myponga Reservoir as a case study, the importance of rainfall patterns and hydrodynamics for the determination of raw water quality for potable water production.

Myponga reservoir

Description/characteristics

Myponga Reservoir (S 35° 21' 14", E 138° 25' 49"), situated 70 km south of Adelaide, South Australia (Figure 1a), is a drinking water supply reservoir with a maximum depth of 42 m and a volume of 26,800 mL at full supply level. It has a catchment of approximately 124 km² of mixed land use, including improved pasture for dairy, beef and hay production, plantations of *Pinus radiata*, and patchy remnant native vegetation. A survey of dominant land use estimated 62% livestock grazing and 24% dairying (Thomas et al., 1999). The reservoir is artificially destratified, which reduces the release of contaminants from sediments (Brookes et al., 2000), and hence the nutrient load to the water column is dominated by catchment sources. Summer chlorophyll maxima range from 10 to 50 mg m⁻³, while annually, water temperatures range from 10°C to 25°C. The dissolved organic carbon concentration is 10–12 mg L⁻¹ with high color (55–65 HU) and generally low turbidity (<5 NTU). The water treatment plant is a dissolved air flocculation flotation type (DAFF) supplying similar to 10 ML day⁻¹ in the winter months and similar to 50 ML day⁻¹ in the summer months.

Nutrient load

The annual load from the catchment of nitrogen and phosphorus varies significantly with the streamflow

Myponga Reservoir, South Australia: The Influence of Nutrients, Phytoplankton, Pathogens, and Organic Carbon on Water Quality, Figure 1 (a) Location of the reservoir in South Australia, Australia. (b) The catchment of Myponga reservoir showing the sub-catchments and water courses. Myponga river is the main water course in catchment zone 1. (c) Schematic of Myponga reservoir showing the locations of the dam wall, aerator, meteorological stations (Met1, Met2), and the inflow of Myponga River.

regime, determined by the interannual variability in rainfall (Linden et al., 2004). Calculating the mass balance of nutrients between the inflows and the offtakes revealed that Myponga Reservoir retained 80–90% of the inflowing phosphorus in two consecutive years with similar rainfall, yet different streamflow (Table 1). In 1999, there were fewer rainfall events that generated high streamflows and subsequently reduced the transport of nutrients from the catchment. In 2000, almost 40% of the annual catchment load of phosphorus was delivered during flows above 200 ML day⁻¹. This work identified that remedial works for reduction of catchment loads, such as wetlands or ponding basins, must function at flow rates greater than 25 ML day⁻¹, as this is the flow regime when the majority of phosphorus is delivered to Myponga Reservoir (Table 2). The annual loads of nutrients themselves do not present a threat to water quality, but the consequences for the growth of phytoplankton are important from a water quality perspective.

Phytoplankton

Concentration

The absolute concentration of algal cells in the reservoir raw water is relevant for the water treatment as algal-derived organic carbon can be precursors for disinfection by-products (Graham et al., 1998) and contribute substrates for the formation of biofilms in distribution systems. The relationship between phosphorus loading and maximum chlorophyll concentration in lakes and reservoirs is well known (Dillon and Rigler, 1974; Harris,

1994; Vollenweider, 1975). Chlorophyll responded in a predictable manner to phosphorus concentrations in Myponga Reservoir (Figure 2), and this was largely driven by external inputs. Some years were considered to be outliers, where the linear relationship between phosphorus concentration and peak chlorophyll did not hold. In 1988, the dry spring meant that the supply of phosphorus and the phytoplankton growing season were asynchronous. The strong stratification observed in 1993 resulted in a larger than normal internal load that decoupled the relationship between Chl *a* and total phosphorus. Since 1994, additional commitment of resources to artificial destratification has probably prevented this from occurring again (Brookes et al., 2000).

Composition

The composition of the phytoplankton community has great bearing on water quality. The presence of cyanobacteria (blue-green algae) is a concern as they can produce compounds that taint the taste and odor of water and several species produce toxins (Steffensen et al., 1999). Many cyanobacterial species produce gas vesicles which are hollow gas-filled structures in cells which provide buoyancy and reduce sedimentation losses. The gas vesicles confer an advantage during periods of water column stability (Walsby, 1994) when denser species tend to sink. *Anabaena circinalis* seasonally compromises the esthetic raw water quality in Myponga Reservoir by producing geosmin particularly during periods of shallow vertical mixing when its numbers rapidly increase (Lewis

Myponga Reservoir, South Australia: The Influence of Nutrients, Phytoplankton, Pathogens, and Organic Carbon on Water Quality, Table 1 Annual catchment load and rainfall characteristics for Myponga reservoir in 2 years where the nutrient load from the catchment was studied. The outlier years of 1988 and 1993 are not included in the regression and are discussed in the text.

et al., 2004). Artificial destratification, with bubble plume aeration and mechanical mixing, has been applied at Myponga Reservoir, with the combined goals of reducing cyanobacterial growth and controlling iron and manganese release from the sediments by preventing hypoxia. Artificial destratification does not always prevent or reduce the growth of problematic cyanobacteria (Antenucci et al., 2005b), but the principle of its influence on community dynamics by changing the vertical mixing regime is sound and it is often effective (Heo and Kim, 2004; Visser et al., 1996). The composition of the phytoplankton community at Myponga Reservoir was investigated with a monitoring program, a series of ecophysiological investigations of photosynthetic and growth responses, and modeling studies.

Important taxa found in the phytoplankton community at Myponga include cyanobacteria (e.g., *Anabaena*, *Microcystis*, *Phormidium*, *Planktothrix*, *Aphanocapsa*, *Oscillatoria*), Chlorophytes (e.g., *Ankistrodesmus*, *Chlamydomonas*, *Chlorella*, *Oocystis*, and *Scenedesmus*), Diatoms (e.g., *Cyclotella* and *Nitzschia*), Chrysophytes (e.g., *Chroomonas*, *Cryptomonas*), and dinoflagellates (e.g., *Peridinium*). It is generally dominated by green algae and diatoms, which rely on turbulence to remain entrained; the conditions when cyanobacteria grow to significant biovolumes is restricted to short periods each year (Figure 3) when there is a shallowing of the surface mixed layer and high nocturnal air temperatures that inhibit lake cooling. Ordination between the phytoplankton community dynamics and physical and chemical conditions revealed that the dominant processes determining the composition of the phytoplankton community were the surface mixed layer depth and the concentration of inorganic nitrogen and filterable reactive phosphorus. Due to stable periods with shallow mixing in the summer

periods, the destratification system was unable to mix sufficiently deeply to restrict *Anabaena* growth by light limitation. Experimental investigation of *Anabaena* grown in bottles at different depths and, therefore, light doses, suggested that, at euphotic to mixed layer depths ratios (Z_{eu}/Z_{mix}) above 0.2, this species would grow rapidly at summer irradiances.

Modeling the growth of *A. circinalis*

To expand on the empirical understanding of the occurrence of cyanobacteria within the reservoir, the growth of these problematic organisms can be modeled, providing a useful management tool (Lewis et al., 2004). Application of a physical-biological coupled model, such as DYRESM-CAEDYM, allows the testing of destratification scenarios to evaluate their effectiveness to attenuate the growth of cyanobacteria. Lewis et al. (2004) found that the destratification systems employed at Myponga Reservoir reduce the peak *A. circinalis* biomass to approximately a third of their potential peak biomass in the absence of mixing. Despite this, the use of algicides remained a reservoir management strategy for these periods. Alternatives, such as advanced treatment processes, such as ozonation and activated carbon may be considered to deal with episodes of geosmin in source waters. However, the contribution of artificial destratification to the control of this threat to water quality was demonstrated. Recently, the bubble plume aerator has been switched off during periods of very high cyanobacterial abundance. This allows the cells to float upward where they tend to form “blooms” at the surface and subsequently lyse. This protects the deep offtakes from high concentrations of cyanobacteria and prevents them from entering the treatment plant. Residual geosmin in the source water is removed with powdered activated carbon dosed at the intake to the water treatment plant.

Pathogens

The pathogens that threaten water quality originate from catchments, generally as the result of contamination by microbes (*E. coli*, *Clostridium*, etc.) or protozoa (*Cryptosporidium* spp., *Giardia* spp.) from livestock or sewage systems. Consequently, rain event inflows present a significant challenge to water quality as they carry these hazards into the reservoir. Pathogens can be inactivated by sedimentation, exposure to UV light, grazing, and natural mortality (Brookes et al., 2004). These processes are influenced by the length of time the pathogens spend in the reservoir and by their distribution. This, in turn, is determined by the processes of dispersion, dilution, horizontal and vertical transport. Of particular importance is the hydrodynamics of pathogen-containing inflows. The behavior of inflows is controlled by their density relative to that of the lake water, such that warm inflows will flow over the surface of the lake as a buoyant surface flow and cold, dense inflows will sink beneath the lake water where they will flow along the submerged reservoir basin

Myponga Reservoir, South Australia: The Influence of Nutrients, Phytoplankton, Pathogens, and Organic Carbon on Water Quality, Figure 3 Sum of biovolumes measured for the different taxonomic groups observed at Myponga reservoir.

channel toward the deepest point. In either case, the inflow will entrain water from the lake, increasing its volume, changing its density, and diluting the concentration of pathogens and other characteristics. In the case of a dense underflow, when its density matches that of the adjacent lake, the underflow will become an intrusion. In some cases, the underflow is denser than any water in the lake, and it will flow all the way to the deepest point (Figure 4). This is of particular interest, as in the majority of drinking water reservoirs the deepest point is often where the offtake to drinking water supply is located (i.e., at the dam wall). Given that oocysts will survive longest in cold and dark water, this underflow mechanism can potentially produce the greatest risk. Using knowledge of the properties and behavior of riverine intrusions allows the extraction of water from outside of this zone and will minimize the pathogen risk.

Inflow hydrodynamics

A comprehensive case study of the movement of pathogens from the catchment to the reservoir offtake was undertaken at Myponga Reservoir. The reservoir had two meteorological stations installed to measure wind and solar radiation and thermistor chains that were used to assess the hydrodynamic conditions within the water body (Figure 1c). Flow and temperature were also measured in the inflow of the main river at the v-notch gauging weir. An intense sampling program followed a large rainfall event (58.4 mm) and a hydrodynamic modeling study was performed (Figure 5). Despite the mean retention time based upon abstraction rates being approximately 3 years, the riverine intrusion reached the dam wall within 36 h (Brookes et al., 2005). Targeted sampling of the intrusion revealed the heavy pathogen load carried by the intrusion (Brookes et al., 2005; Hipsey et al., 2006). This

Myponga Reservoir, South Australia: The Influence of Nutrients, Phytoplankton, Pathogens, and Organic Carbon on Water Quality, Figure 4 Formation of intrusions during inflow events. The density of the water is represented by the shading. The coldest and most dense water is shaded the darkest. Reservoir density stratification has been represented as an arbitrary linear gradient. The depth of formation of the riverine intrusion will correspond to the depth in the reservoir of equivalent density.

experiment allowed the reexamination and revision of existing pathogen monitoring regimes by demonstrating the correlation, or indeed the lack thereof, between the hydrodynamic distribution of surrogates of fecal contamination and the pathogen oocysts (Brookes et al., 2004, 2005; Hipsey et al., 2006). The invaluable data provided by the experiment assisted in the development and validation of models of transport and dilution of microbial

pathogens during riverine transport (Antenucci et al., 2005a; Hipsey et al., 2004, 2008). The fecal coliforms were associated with particles (Hipsey et al., 2006), while the *Cryptosporidium* oocysts were free floating (Hipsey et al., 2004), and the differences in settling behavior means that using surrogates alone could result in underestimation of protozoan pathogen dilution and therefore overestimation of risk reduction (Brookes et al., 2005). The combination of knowledge of reservoir dilution dynamics is therefore important for calculating the effectiveness of the reservoir as a barrier to pathogen intrusion into the water treatment system. Complex three-dimensional hydrodynamic models provide the best understanding of individual events but may be impractical for informing management responses in real time without considerable investment. Simpler dilution models that capture the key processes are available and are a potential management tool (Antenucci et al., 2005a).

Natural organic matter

Natural organic matter (NOM), the complex polymerized residuals of decaying biomass (predominantly vegetation), imparts color to waters and is a precursor for disinfection by-product formation. In waters of low turbidity, it is a major target for removal by the water treatment process and that which is not removed contributes to the growth of biofilms in the distribution system and increases chlorine demand. Being chemically indistinct, it is useful to apply characterization methods to NOM, which describe its properties according to size (HPSEC; Chow et al., 2009), functionality (resin fractionation; van Leeuwen et al., 2002), and suitability as a microbial substrate (microbial regrowth potential; Page et al., 2002). The quantity and character of organic matter found in a drinking reservoir is the product of the sources of organic matter and the processes acting upon it. Aspects of organic matter dynamics including catchment loads, hydrodynamic transport, and microbial degradation were investigated in the Myponga Reservoir system (catchment and reservoir) with a flow weighted monitoring program in the main sub-catchment, an intensive investigation of the same flow event, as described in the section on “Pathogens” above, and modeling studies (Linden, 2007).

The sources of NOM in reservoirs are allochthonous (derived from outside the reservoir; i.e., the catchment) and autochthonous (produced within the reservoir; i.e., by phytoplankton and aquatic macrophyte growth). River discharge often has a significant influence on the organic carbon concentration in flowing water (Schlesinger and Melack, 1981), and therefore the delivery of allochthonous NOM. This influence has been attributed to the flushing and mobilization of old soil water (Pearce, 1990; Pearce et al., 1986). Often a hysteresis is observed with organic carbon concentrations being greater on the rising hydrograph than on the falling hydrograph (Grieve, 1984; Moore and Jackson, 1989). However, the opposite is generally observed at Myponga Reservoir (see Figure 6

for an example). In total, nine peak flow events were analyzed for concentration-flow (*C-Q*) hysteresis by the methods of Butturini et al. (2006). These observations suggested that there was generally a temporal separation in the surface and ground water contributions to flow occurring in the Myponga River catchment and that significant hysteresis occurred. Seven of the nine events analyzed had anticlockwise hysteresis rotations implying increased DOC concentrations on the falling hydrograph. Such information is vital to inform management responses; the greatest increases in NOM concentration in the inflowing river water may be found on the falling hydrograph and follow the threat caused by pathogens carried by the flow front by many hours (Linden, 2007).

The flow event shown in Figure 6 was the same event as was intensively sampled as described in the section on “Pathogens” above. Samples were also collected for determination of NOM properties to assess the changes in raw water quality. Empirical modeling of recommended coagulant doses (van Leeuwen et al., 2005) predicted only small increases in the coagulant dose requirements for the observed changes in raw water quality on the basis of NOM and turbidity changes (7.2% increased cost in treatment chemicals); 40% of this increased coagulant dose was attributable to changes in the NOM. There was a relatively small impact of raw water quality in this event; however, investigations in other systems have demonstrated greater impacts of inflows on NOM character and its amenability to removal by water treatment (Hobson et al., 2010). Reservoirs seem to generally provide a significant barrier or buffer for changes in raw water quality from the perspective of NOM as generated by riverine inflows.

The longer term perspective of the benefits of water storage reservoirs should also be considered as they retain significant quantities of organic matter. The annual allochthonous organic carbon load at Myponga Reservoir was estimated to be 240 ± 110 t (mean 1999–2003 $\pm$ SD) on average, four times greater than the estimated autochthonous carbon load of 60 ± 34 t (Linden, 2007). However, in a year of very low rainfall (2002), the estimated autochthonous and allochthonous loads were similar. Therefore, in terms of mass, the catchment delivers a significantly greater amount of organic carbon than the water storage process generates. The mass of organic carbon taken into the WTP was similar to 100 t/year, while the loss of a similar amount could be attributed to consumption by the microbial community, as estimated by applying existing models (Cole and Pace, 1995; del Giorgio and Cole, 1998). The application of models of photomineralization (Vahatalo et al., 2000) implied the loss to this process was an order of magnitude less than microbial metabolism (see Figure 7 for budget structure; Linden, 2007). In short, reservoirs provide significant ecosystem services for the provision of better raw water quality over short and long timescales from the perspective of natural organic matter.

Conclusions

Understanding the processes that determine raw water quality at the outlet of the reservoir is a multidisciplinary challenge. Options for the management of reservoir water quality are available in both the catchment and the reservoir; however, critical control points are generally limited to the reservoir offtake. A holistic view of the role of reservoirs in water quality can improve water quality by providing the water treatment plant with the best raw water quality possible, for a given system, and give it the best chance of providing the best quality water to the customer tap.

Acknowledgments

The South Australian Water Corporation that managed the water supply during the time of the research conducted must be duly acknowledged for its commitment to water quality research, in conjunction with the Cooperative Research Centre for Water Quality and Treatment. The criticism of management practices at the reservoir must be considered as criticism of the water industries' best available management options. Further, the authors' views consist of focussed examination of particular events and periods of time, which they consider representative, but cannot always consider all aspects of reservoir management, such as economic and legal constraints. The authors would like to thank all their colleagues who have worked with them including David Lewis, Rod Boothey, Allan Brown, Rudi Regel, John Van Leeuwen, Rolando Fabris, Peter Hobson, Jason Antenucci, Dennis Steffensen, and Don Bursill.

N

NAHUEL HUAPÍ, LAKE

Rhodes W. Fairbridge (Deceased)

Definition

Nahuel Huapi is a glacial lake in the Patagonian Andes, near the boundary with Chile, at 765 m (2,516 ft) elevation. It is located in Neuquén Province on the edge of Rio Negro Province. Its area is 549 km² (212 mi²). It is 65 km (40 mi) long, 8 km (5–6 mi) wide, and up to 300 m (1,000 ft) in depth. It has several fjord-like arms. An area of 7,848 km² (3,030 mi²) is protected as a national park. In the SW is Mt. Tronador (over 3,350 m), which is covered by glaciers. Its scenery is spectacular, and the area is now a tourist destination, the town of San Carlos de Bariloche being situated on the SE shore. It is drained by the Limey R., which discharges into the Rio Negro.

NASSER LAKE

Mohamed I. Balah
Suez Canal University, Port Said, Egypt

Site

Lake Nasser lies between latitudes 23°58'N and 20°27'N and longitudes 30°07'E and 33°15'E (Kim and Sultan, 2002; Ball, 1927; Dasco 1998a, b). The total length of the reservoir is about 500 km, with 150 km in Sudan (Lake Nubia) and 350 km within the Egypt's borders (Kim and Sultan, 2002; Ball, 1927; Dasco, 1998a), see Figure 1.

The lake has a surface area of 600 km² and an average width of 12 km (Dasco, 1998b). The total storage capacity

of the lake is 160 × 109 m³, of which nearly 20% is considered dead storage (i.e., water is not released from this part of the lake regardless of the downstream needs). This zone receives and retains sediments during flooding.

The lake is home to an impressive variety of birds, mammals, and reptiles. More than 100 species of birds live on its shores, including wild duck, Egyptian geese, pelicans, herons, egrets, and various species of hawks, kites, and falcons. Monitor lizards, Dorcas gazelle, jackals, desert fox, and other smaller desert mammals can also be observed.

Lake Nasser has, arguably, the best freshwater fishing in the world for both Nile perch and tigerfish. There are also several subspecies of catfish and two kinds of tilapia. In all, there are around 32 species of fish in the lake. The two main fishing techniques used are trolling and shore fishing. Shore fishing requires more skill than trolling and usually yields more fish. Although trolling is more popular, larger fish can be caught shore fishing, the record catch being 179 lbs.

Because the Lake Nasser reservoir is approaching its maximum storage capacity, the depressions west of Lake Nasser in the southwestern Desert of Egypt (Figure 1) are used as a natural flood diversion basin to reduce possible downstream damage to the Nile Valley caused by exceptional flooding (Kim and Sultan, 2002).

The major strategic units and the ground water table level in Lake Nasser are shown in the hydrogeologic map (Figure 2a) and the schematic cross section (Figure 2b) along line A-A.

Climate change assessment

Changes in water level interact with the physical features of Lake Nasser to yield both positive and negative geoenvironmental impacts (El Gammal, 2010; Nile Research Institute (NRI), 2006; El-Sersawy and Farid, 2005). Two strangle portions in the course of the lake are examined. One is the El Madiq strangle zone, where sands fall and drift on the stream gradient to the narrow course

Nasser Lake, Figure 1 Moderate resolution imaging spectroradiometer satellite image acquired February 19, 2000 (Kim and Sultan, 2002).

that appears as shallow water on satellite imagery. The other is the entrance of the lake, a site of new delta initiation, with maximum thickness concentrated in a zone lying between 350 km and 420 km of the dam. Two positive impacts have been found: in Allaqui, the difference in water area between 1987 and 2000 was 91.9 km², and the difference in water extension was 25.54 km.

In Allaqui, fine soil in an area about 30,121 km² in the basin can be cultivated. The saturated water zone in Kurkur is close to the land surface and subject to

transpiration and evapotranspiration. Kurkur vadose water can flow to the lake course and interflow water can migrate back to the land surface to evaporate. An area of 392 km² available for agriculture protects the Kurkur area from evaporation (El Gammal, 2010).

To detect changes in the water level in Lake Nasser a remote sensing technique was used with Landsat TM images from 1972, 1987, 2000, 2003, and 2008 using the ArcMap program and Geographic Information System (GIS) (Figure 3).

Nasser Lake, Figure 2 Simplified hydrogeologic map of the study area (Kim and Sultan, 2002). (a) Major hydrogeologic units, model boundaries, and locations of pumping and piezometric wells. (b) Northwest-southwest, trending schematic cross section, along line A-A in panel (a).

Strangle problems

El Madiq strangle (Gorge) zone

In the course of River Nile, the shallow water gorge portion stretches from El Madiq to Kurusku, 27.6 km in length and 2.7 km average width (including the El Madiq

strangle portion, which is 1.1 km width and 4.6 km in length) (Figures 3 and 4).

Before the high dam, the water velocity increases in speed, with more erosion in flanks, and passes toward the north. After the dam, the water velocity decreases

Nasser Lake, Figure 3 Change detection on Lake Nasser in multi-temporal dates (El Gammal, 2010).

and sand deposition has increased due to change in global climate. Water goes through narrow, incised wadis (khors) in the eastern bank with altitude 150 m in troughs (Figure 4). These khors are traced in hard Nubian sandstone, which is already saturated with water and is considered an underground water reservoir before the dam construction.

Sediment concentration

Before construction of the High Dam in 1964, about 93% of the total average annual suspended load of 124 million tons/year was carried out to the Mediterranean Sea. After the High Dam construction, flood discharge of the Nile downstream has been greatly modified and more than 98% of the total suspended load was retained within the reservoir and the total amount of sediment transported

downstream of the dam dropped to only 2.5 million tons/year due to a decrease in water velocity.

In 2000, the average water velocity was 0.52 m/s at 487 km south of the High Dam and in 2001, it was decreased from 0.46 m/s at the entrance of the lake to 0.04 m/s.

The deposited material within the Egyptian border was equal to 56 Mm³(million cubic meters) between February 2007 and March 2008 and the total sedimentation volume through March 2008 was 1123 Mm³. In Sudan, the sedimentation between February 2007 and March 2008 equaled 200 Mm³ and the total sedimentation volume through March 2008 was 5161 Mm³ (Nile Research Institute reports 2000 and 2006).

At Halfa in 2006, the total volume of sedimentation was 1.673 Bm³ (billion cubic meters) at water levels less than

Nasser Lake, Figure 4 El Madiq shallow zone and sand encouragement on Lake Nasser from the Western Desert (El Gammal, 2010) (Note: The arrows indicate wind direction and sand movement).

147 m, and 3.345 Bm³ between water levels 147 m and 175 m; there was no sedimentation above water level 175 m. Consequently, the water can spillway to the north at 170 m. The total volume of sedimentation in the lake was 6,284 Mm³ from 1964 to 2008 (18% in Egypt and 83% in Sudan), while in cross section 26 (the second cataract at 357 km from the High Dam, Figure 5) it was 1,037.44 Mm³ during the same period in Halfa, forming a new delta from 1968 to 2008 in a zone including the following localities;

- Gemi (372 km from the dam), sedimentation thickness = 59.82 m
- Qengari 6 (394 km from the dam), sedimentation thickness = 57.89 m
- Murshed 3 (378.5 km from the dam), sedimentation thickness = 54.49 m
- Old Second Cataract, sediment thickness = 52.10 m

An estimated annual average of 160 million tons of sediment reached El-Gaafra Gauging Station (34 km to the north of the High Dam downstream) during the period from 1904 to 1963; the annual sediment load varied from 50 million tons to 228 million tons per year (Nile Research Institute (NRI), 2006).

The suspended sediment concentration peaks at El-Gaafra have dropped from 3,000 ppm before lake

initiation to only 50 ppm after the construction of the lake (El-Sersawy and Farid, 2005).

Evaporation estimates

An update of evaporation estimates, using local meteorological and hydrological data collected from instrumented platforms (floating weather stations (FS)) at three locations on the lake, Raft, Allaqi, and Abusembel (respectively, at 2, 75, and 280 km upstream of the Aswan High Dam), is given in Figure 6 (Elsawwaf et al., 2010).

Results from six conventional evaporation quantification methods were compared with the values obtained by the Bowen ratio energy budget (BREB) method. The results of the BREB method showed that there is no significant difference between the evaporation rates at Allaqi and Abusembel. At Raft, higher evaporation rates were obtained, which were assumed to be overestimated due to the high uncertainty of the Bowen ratio (BR) parameter. The average BR value at Allaqi and Abusembel was used to eliminate this overestimated evaporation. Variance-based sensitivity and uncertainty analyses on the BREB results were conducted based on quasi- Monte Carlo sequences (Latin hypercube sampling). The standard deviation of the total uncertainty on the BREB evaporation rate was found to be 0.62 mm day⁻¹.

Nasser Lake, Figure 5 Illustration of the deposited bed inside Lake Nasser, prepared from data collection of the mentioned references.

The parameter controlling the change in stored energy, followed by the BR parameter, was found to be the most sensitive. Several of the six conventional methods showed substantial bias when compared with the BREB method. These were modified to eliminate the bias. When compared with the BREB-based values, the Penman method showed most favorably for the daily time scale, whereas for the monthly scale, the Priestley-Taylor and the deBruin-Keijman methods showed best agreement. Differences in mean evaporation estimates of these methods (against the BREB method) were found to be in the range 0.14 and 0.36 mm day⁻¹. All estimates were based calculations at the daily time scale covering a 10-year period (1995–2004) (Figures 7 and 8).

Impact of summer thermal stratification on depth profile of phytoplankton productivity, biomass, density, and photosynthetic capacity

In winter, there is a complete upwelling in the water body; in the summer, it is clearly thermally stratified (Abd El-Monem, 1995, 2008; Abdel and Goma, 1993; Entz and Latif, 1974; Reynolds, 1984; Chang and Bradford, 1985; Tilzer, 1983; Carpenter et al., 1987; Grobbelaar and Stegmann, 1976; Robarts, 1984; Haberl, 2007). Depth profile of summer stratification at the upper 15 m was investigated at four different sites. Temperature

amplitude reached about 10°C, whereas oxygen concentration was about 7.491 mg O₂ l⁻¹.

The epilimnion layer was extended to 10 m depth, whereas the metalimnion went from about 10–15 m, and the hypolimnion was below that. Bands of stratification were affected with the inflow of the River Nile at the south. Peak maximum of chlorophyll a, phaeophytin, and standing crop was recorded at 10 m. Net primary productivity was irregular along the depth profile. Superficial water had climax photosynthetic capacity and declined downward. Integrated column productivity was correlated with that equivalent concentration of chlorophyll a. Khore Korosko exhibited the highest integrated productivity rate (315.9 mg C m⁻² h⁻¹) and photosynthetic capacity (24.4 mg C mg Chl⁻¹ h⁻¹) among the studied sites.

Layering width of water stratification and its temporal occurrence were affected by current and physics of flooded water. Thus, the epilimnion is usually shallow in the north and becomes deeper toward the inflow of Nile floodwater at the south.

To represent water body and depth profile in the main channel and khors during summer thermocline (during July 2005), samples were collected from the upper 15 m depth (the approximate mean depth of the photic zone) at different depths: 0, 3, 5, 10, and 15 m from four sites. One represented the main channel and was located in

Nasser Lake, Figure 6 Map of the Lake Nasser area showing the floating stations (FS) sites and the major physical features of Lake Nasser (Elsawwaf et al., 2010).

El-Madiq. The other three represented the khors (Kalabsha, Korosko, and Tushka) and were located in the deepest position. The sampling sites are shown in Figure 9.

Results were expressed at the given depths per unit volume (m^3) and were integrated to calculate it per unit area (m^2) for that layer. The main morphometric variables of the selected locations are illustrated in Table 1, as reported in Bishai et al. (2000).

Temperature and dissolved oxygen amplitudes, and integrated values of some biological variables for water columns at the study sites in Lake Nasser during summer stratification are indicated in Table 2.

Figure 10 shows water visibility (c) at the studied sites in Lake Nasser, and Figures 11, 12, 13, 14, 15, 16 and 17 indicate depth profile of water temperature ($^{\circ}\text{C}$), dissolved

oxygen ($\text{mg O}_2 \text{ l}^{-1}$), chlorophyll a (mg Chl a m^{-3}), phaeophytin (mg m^{-3}), net primary productivity ($\text{mg C m}^{-3} \text{ h}^{-1}$), assimilation rate ($\text{mg C mg Chl}^{-1} \text{ h}^{-1}$), phytoplankton density ($\text{unit m}^{-3} \times 10^6$), respectively, during summer stratification.

In this study, water visibility in khors was mainly biologically controlled because it was inversely associated with integrated phytoplankton density in that water column ($r = 0.75$). It increased downstream, with a maximum of 3.15 m in Kalabsha. In comparison with the previous investigations, (Abd El-Monem, 1995) found that water turbidity at the northern region of the main channel (downstream) is biologically controlled, whereas on the southern side it was affected with the suspended inorganic matters carried with the flooded water.

Nasser Lake, Figure 7 Analysis of measurements at three locations on the lake (Raft, Allaqi, and Abusembel). (a–c) Daily average BR value for the period 1995–2004 at Raft and Allaqi stations and for the period 2000–2004 at Abusembel station. (d–f) Vapor pressure difference between the lake surface and 2 m above the lake surface at Raft, Allaqi, and Abusembel stations for the same periods. (g–i) Daily average temperature difference between the lake surface and 2 m above the lake surface at Raft, Allaqi, and Abusembel stations for the same periods.

In winter, there is a complete upwelling in the water body, and the lake lies under unstratified conditions. During summer, however, the water column was thermoclined and the temperature of the water body increased upstream. In the upper layer, water temperature rose to 31.8°C. Difference in water temperature (amplitude) in the 15 m layer varied from 1.4°C in Kalabsha to 5.3°C in Toshka. Its amplitude was increased upstream, but it could extend farther down to 15 m (the studied zone) in the northern khors. This agrees with (Abdel and Goma, 1993).

On this concept, those who surveyed the lake during the filling phase (1972–1973) (Entz and Latif, 1974) reported that the time of total circulation ends in March or April when the stratification starts to develop. The depth of metalimnion is usually initiated at 12–17 m depth, with a peculiar decline to the south. Thus, the epilimnion is usually shallow in the north section and becomes deeper towards the inflow of Nile River water at the south. Under stratified conditions, temperature of the epilimnion rises to 25–29°C. Higher temperatures are unusual, except on very calm days when, within the upper 1–1.5 m, the temperature can rise to 30°C. This may be caused by the decrease of thermal stability of the lake towards the south and the inflowing flood water. Stratification is usually

dissolved from the south, starting in September and completed gradually towards Aswan in November.

Spatial distribution of dissolved oxygen (DO) along the water column showed that oxygen distribution has a similar trend as that of the temperature. Thus, water depth up to 10 m was well oxygenated and represented the epilimnion layer, while metalimnion can be extended to 15 m depth, and hypolimnion layers below that. The value of hypolimnion was the widest near the High Dam; and diminishes to the south. Concerning yearly cycling of DO, (Entz and Latif, 1974) found that water is saturated to the bottom during winter circulation. From March, when the enormous development of the phytoplankton starts, there is a strong increase in DO content within the surface layer up to 14–18 mg O₂ l⁻¹. However, because of the increased thermal stability, the metalimnion is formed and the hypolimnion becomes increasingly poorer in oxygen. The gradient of DO in the metalimnion layer, which occurs when the hypolimnion becomes severely deoxygenated, creates a chemically diverse layer. The main loss of oxygen in that layer is probably due to decomposing sinking plankton organisms forming the so-called plankton rain. The bacterial activity might be the most vivid just below the metalimnion.

Nasser Lake, Figure 8 Daily evaporation estimates from Lake Nasser. (a) 109 months at Raft station using BR values from Raft station. (b) 109 months at Raft station using BR values from Allaqi and Abusembel stations. (c) 58 months at Allaqi station. (d) 41 months at Abusembel station, averaged per month, as determined by the BREB method, 1995–2004. Error bars indicate the estimated maximum uncertainty (about 10%) of the BREB.

In warm tropical water, small temperature differences have disproportionately large effects on the density of consumers and hence on the stability of stratification (Talling, 1957). This study reveals that the upper 10-m layer represents the critical zone in physical, chemical, and biological activities along the water column during summer. In spite of a limited decrease in water temperature, that depth includes a noticeable variation in phytoplankton activity among the water column. It includes the peak of phytoplankton density, biomass (Chl *a*), and phaeopigments. It is also still well oxygenated. These parameters sharply declined downward.

In aquatic ecosystems, phytoplankton density, biomass, and photosynthetic capacity may indicate the eutrophic status of a lake. This study showed that depth profiles of phytoplankton standing crops are associated with water thermal stratification. Phytoplankton density is much greater in epilimnion than in hypolimnion. Epilimnion was turbulent, and phytoplankters are maintained in suspension in it. Reynolds (Reynolds, 1984) established that many cellular processes of phytoplankton are temperature-dependent, especially between 25°C and

40°C. Other physical, chemical, and biological (heterotrophic organisms) factors can affect the temporal distribution of phytoplankton in the lake's water. Grazer and predator populations may control phytoplankton populations directly and indirectly by large zooplankton, which can transport significant quantity of nutrients from the epilimnion layer (Longhurst and Harrison, 1988). Thus, regional variation of phytoplankton reflects its response to varying environmental conditions and is affected by advection, turbulence, and grazing, (Chang and Bradford, 1985).

Spatial and vertical distributions of net primary productivity in the lake water vary and reflect the response of phytoplankton to ecological variables. Values were limited between 31.9 and 74.4 mg C m⁻³ h⁻¹. The trend of its fluctuations in water column was irregular. Maximum production value was detected in surface water at El-Madiq and Korosko, whereas it was at 3 and 10 m at Kalabsha and Toshka, respectively. Integrated column productivity for the study depths revealed that Korosko was the highest productive area (947.8 mg C m⁻² h⁻¹), whereas El-Madiq was the lowest (713.9 mg C m⁻² h⁻¹). It was correlated with an equivalent concentration of Chl *a*.

Tilzer (1983) reported that light fractions absorbed by algae increase with biomass but decrease with rising inorganic turbidity.

Generally, variability of primary productivity in the given results cannot be related to specific factors. There may be a variety of factors controlling primary productivity, mostly abiotic in nature, such as light, climate, turbulence, and nutrients (Tilzer, 1983). It was mainly limited by light penetration (Secchi depth) and turbidity when nutrients are in excess of growth demands. Nevertheless, primary productivity control by the food web has been shown to be sometimes as influential as the aforementioned abiotic factors (Carpenter et al., 1987). Water movement can result in marked variations in interception

of light by phytoplankton (Grobbelaar and Stegmann, 1976). One therefore has to pay attention to other biotic components of the lacustrine ecosystem if a clear picture of the primary productivity is to be achieved. This is especially true for hypertrophic ecosystems where physical features are suspected to control primary productivity in view of nutrient excess (Roberts, 1984). Extensive human land use results in various levels of impact on actual net primary production. In a few regions, such as the Nile Valley, irrigation has resulted in a considerable increase in primary production (Haberl, 2007).

Nasser Lake, Figure 18 Fish Landing from Lake Nasser from 1965 to 2005 (Béné et al. 2009).

Fisheries production

Lake Nasser is one of the main sources of fishing in Egypt (Abd El-Monem, 2008; Entz and Latif, 1974; Béné et al., 2009). Variability of the entire studied parameters, in the water budget during summer stratification, are greatly affected on the seasonal distribution of fishes, and can be controlled on fisheries and fishing activities during the whole year. In addition, the expected fish yield and its sustainability can be expected from the primary productivity of the lake. Because Entz and Latif (1974) mentioned that fish usually avoid water layers containing less than 2 or 3 mg O₂ l⁻¹, and the same is true for fish food organisms. So fish searching for food usually avoid the hypolimnion, and choose the epilimnion for a habitat. But they even don't like that if the water temperature increases quickly. Therefore, most of them avoid the upper 1–2 m, and thus most of the fish may be located in summer time (during the stagnation period). Of course, there are typical littoral fish species that come to the very shallow water near the shore to find their best conditions for feeding. In winter, the fish spread throughout the lake water.

Fish landing from Lake Nasser from 1965 to 2005 is presented in Figure 18. The total fish landing increased with increase in water level in the lake from 1965 to 1981 to reach 35,000 t in 1981, then decreased again from 1981 to 1986 as a result of drought and subsequent decreases in the lake water level. Starting from 1986, fish landings showed abrupt changes that were not related to water level but due to price fixation and consequent smuggling of fish (Béné et al., 2009).

NILE BASIN, LAKES

J. V. Sutcliffe
 Goring on Thames, Reading, UK

Introduction

The Nile is the longest river in the world at about 6,700 km and extends over much of northeastern Africa, from 4° S to 32° N; it drains an area of nearly 3 million km². As Rushdi Said (1993) has shown, the basin is a relatively recent development; the longitudinal profile reveals a series of flat reaches in basins which evolved independently but are now linked by steep channels. The East African basin of the White Nile contains almost all the lakes of the Nile basin; it is relevant that this portion of the basin originally drained west toward the Congo.

Because the Nile basin is so extensive, the rainfall is extremely variable, both in terms of annual total and of seasonal distribution. The main areas where there is a surplus of rainfall over evaporation, giving rise to significant runoff, are the Lake Victoria and Albert basin in East Africa, and the western part of the Ethiopian highlands where average annual rainfall averages from 1,200 to 1,500 mm, and runoff is drained by the river Baro, the Blue Nile and its tributaries, and the Atbara. The major climate difference between these two areas is that the seasonal distribution of rainfall in the East African basin is bimodal, with rainfall seasons around April and November, while the Ethiopian basin has in general a single rainfall season around July–August. Because this effect is due to the annual migration from south to north of

the Intertropical Convergence Zone (ITCZ), there is also a transition between these two timings in the northern part of the Lake basin and the southern Ethiopian highlands. Because the Ethiopian highlands experience a long dry season as the converse of the single rainfall season, there is a smaller incidence of lakes in this region, and in fact, Lake Tana is the only major lake in this part of the Nile basin.

Within the East African lake region, the Nile basin contains a number of lakes of different types: Lake Victoria; the lakes of the Kagera basin and Lake Kyoga; and Lakes Albert, George and Edward. Their distribution and morphology depend largely on the geological history of the region, and it is necessary to describe this briefly.

Geological background

The formation of the African Rift has had a major impact on the topography and drainage pattern of the upper White Nile basin in East Africa (Figure 1). Drainage from the Equatorial plateau toward the Congo basin was interrupted by the western arm of the Rift Valley, which gave rise to Lake Albert, Lake Edward, Lake Kivu, and Lake Tanganyika (the last two of which are outwith the Nile basin). In the same way the eastern arm of the Rift valley, which runs through Kenya and Ethiopia, gave rise to Lake Turkana and a number of lakes in central Ethiopia, and diverted the drainage of western Ethiopia, which had drained to the Indian Ocean, toward the Nile in the Sudan. Within the depression between the two arms of the Rift valley, Lake Victoria was formed as a close basin which overflowed at Jinja some 12,500 years ago, and several west-flowing rivers like the Kagera, the Kafu, and the Katonga were reversed in their course (Said, 1993). Figure 1 illustrates the fact that the Kafu and Katonga drain in two directions as a result of their diversion, and the shapes of the drainage pattern of the Kagera and its lakes and Lake Kyoga itself are also a result of this deformation.

The steep escarpment to the east of Lake Albert, and the mountains on the western or Congo flank of the lake, are indicative of its origin in the Rift Valley and form a contrast to the relatively flat surroundings of Lake Victoria and Lake Kyoga.

Water balance of lakes

Given that the rate of open water evaporation is primarily controlled by climate and is likely to be fairly constant over a region, the water balance of individual lakes depends largely on the amount and seasonal distribution of rainfall. There is evidence of variability over periods of years in the rainfall of the East African plateau, and there have been marked changes in the surplus runoff generated by the lake systems of the region. Such changes of regime are usually accompanied by rises in lake levels, and these rises draw attention to changes in the water balance. The most conspicuous example of such a regime change in recent years was the rise in Lake Victoria which

Although fluctuations in lake levels illustrate variations in the water balance of the system, these changes cannot be fully explained without adequate records or estimates of rainfall, evaporation, inflow and outflow, as well as water levels. Because the whole region was not developed until relatively recently, these records are only available for comparatively short periods, and are by no means complete in their coverage.

Available records

The East African lakes have only been known to the international community comparatively recently, as travel up the White Nile or Bahr el Jebel was prevented for many years by the presence of the swamps of the Sudd, which indeed means “barrier” in Arabic. The search for the source of the White Nile was a classic example of exploration during the nineteenth century, and Lake Victoria was reached by Speke from the East African coast in 1858. In 1862, Speke and Grant established that a large river flowed north out of Lake Victoria at Jinja. They then traveled north to reach Gondokoro on the Bahr el Jebel, where they met Baker, who reached Lake Albert in 1864 and established the connection between the Lake Victoria outfall through Lake Kyoga and Lake Albert to the Bahr el Jebel. Little time was wasted before scientific exploration began; Gordon mapped the course of the Bahr el Jebel in 1874, and although access through the Sudan was not possible between 1882 and 1898, climate data and water levels were recorded by Emin and others during this period.

Continuous lake water levels were measured around Lake Victoria from 1896, with a gap in 1897–1898, and these were converted to levels at Jinja (Figure 2), near the outflow channel. However, a number of earlier level observations were collected by Lyons during expeditions between 1899 and 1903, and published in Lyons (1906). By comparing these observations with levels derived from correlation with downstream flow records, a reasonable annual series of lake levels has been extended back to 1870 by Tate et al. (2001).

Similar lake level series have been maintained at Masindi Port on Lake Kyoga from 1912 and at Butiaba on Lake Albert since 1904. Levels are also available for Lake Edward between 1942 and 1978. These records reveal a similar pattern across the whole region, with an isolated rise around 1917 and a more sustained rise after

1961, which has been followed by a gradual fall interrupted by short rises in 1979 and 1997. Evidence from low flow periods at Aswan in Egypt, which depend on outflows from the East African lakes, confirms early observations that lake levels were high in the last quarter of the nineteenth century.

Records of rainfall in the East African basin, apart from observations at major sites, do not cover as long a period. However, there have been sufficient long-term stations around Lake Victoria for a number of attempts to derive a continuous series from 1925. The problem with using lakeside stations to deduce the rainfall occurring over the lake is that the lake is sufficiently large to create its own climate; indeed, Flohn and Burkhardt (1985) have memorably pointed out that the true source of the Nile is not the Ripon Falls or the highlands of Rwanda and Burundi, but the nocturnal cloud above the lake which provides the bulk of the lake inflow.

The establishment of gauging stations to measure river flow requires more organization than rainfall measurements. Although Hurst measured flows on several tributaries of the Kagera in 1926 (Hurst and Phillips, 1938), the Egyptian Irrigation Service began regular measurements of flows from 1940 though levels were measured from 1933. The inflows of the other Lake Victoria tributaries are available from various dates; four of the major tributaries are available from 1956, and almost complete tributary flows were obtained by the WMO Hydrometeorological Survey from 1969 to 1978. This Survey was established to investigate the causes of the rise in the lake system in 1961–1964.

Outflows from Lake Victoria are available from 1896, as the flows were controlled by the control at Ripon Falls, and the rating has been derived from discharges measured downstream and from hydraulic modeling. After the construction of the Owen Falls dam below the Ripon Falls, the outflow through the hydroelectric plant and

Nile Basin, Lakes, Figure 2 Lake Victoria monthly levels, 1896–1998. (From Sutcliffe and Parks, 1999, Fig. 3.2.)

spillway has been constrained to the natural outflow according to this “Agreed Curve.” Between Lake Kyoga and Lake Albert, flows are available at Masindi Port from 1912, and estimates have been derived at Kamdini from 1940, based on more reliable ratings (Sutcliffe and Parks, 1999).

Below Lake Albert, the most reliable flow records are at Mongalla on the Bahr el Jebel, which are available from 1905 to 1983 based on regular discharge measurements; however, these include the flows of the seasonal torrents which join the main river between Lake Albert and Mongalla.

Lake evaporation estimates have generally been based on Penman estimates of open water evaporation.

Water balance of successive lakes

Kagera basin

The Kagera is the main tributary contributing to Lake Victoria, and its basin contains a large number of small lakes. With a basin area of 60,000 km², the river, with its tributaries the Ruvuvu and Nyabarongo, drains much of Rwanda and Burundi as well as parts of Tanzania and Uganda. With a general elevation of 1,200–1,600 m, the basin rises above 2,500 m in the west, where peaks reach 4,500 m; the annual rainfall is less than 1,000 mm in the lower east of the basin, but rises to 1,800 mm in the higher west. A number of tributaries converge above Rusumo Falls, where regional warping and drainage reversal have led to valley courses filled with lakes or swamps totaling some 1,400 km².

There are two rainfall seasons, in February–May and September–November, and the runoff responds with a peak in April in the upper reaches, which is delayed by swamps and lakes to May at Rusumo Falls and July where the river enters Lake Victoria. The river passes extensive areas of swamps and lakes both above and below the falls, but it is easier to deduce the balance of the lower lakes and swamps, which cover about 1,600 km², by comparing inflows and outflows, rainfall, and evaporation (Figure 3). Figure 3a, comparing inflows and outflows for the lower lakes and swamp, shows the lag of about two months, while Figure 3b converts the water balance, including rainfall and evaporation over 1,600 km², into monthly lake levels which correspond with the observed fluctuations.

Lake Victoria

Lake Victoria is the largest lake in the Nile basin and covers an area of 67,000 km² with an average depth of 40 m; formed as it is at the center of the depression formed by the Rift Valley, it has a number of tributaries of which the Kagera is the largest. These drain a total area of 194,000 km² and contribute a total inflow of 23,000 m³ × 10⁶ or an average depth of only 120 mm over the basin; this inflow volume compares with a depth of 343 mm over the lake area. As this compares with an estimated annual rainfall over the lake of 1,858 mm, it is clear that the direct

rainfall is the most important contribution to the lake water balance, but the tributary inflow is the most variable, because the runoff coefficient itself increases with rainfall. The water balance of the lake has been the subject of speculation and investigation over a number of years, but it was not until the inflow of the tributaries was measured after the establishment of the WMO Survey that reasonable estimates could be made, and the background to the unprecedented rise in lake level could be explained. The various components of the balance have been estimated for the period 1956–1978 with sufficient precision for this purpose.

The tributary inflow series has been completed by the Institute of Hydrology in 1985 (Piper et al., 1986) by comparing the almost complete flow measurements by the WMO Survey for the period 1969–1978 with the flows of four major tributaries for the longer period 1956–1978 and deriving monthly multipliers to deduce the total inflow for the whole period. The Kagera inflow, whose timing is different because of lake storage, was added separately.

The lake levels have been measured regularly at Jinja over this period, which includes the dramatic rise in the lake in 1961–1964. The changes in storage can be deduced from the lake area. The lake outflows can be deduced by applying the Agreed Curve linking lake levels with outflows, bearing in mind that the flows through the site were constrained to follow the curve after construction of the Owen Falls dam, where the turbine/sluice records provide an alternative estimate of outflows.

The lake evaporation forms a major portion of the outflow from the lake and, in fact, is similar in amount to the average rainfall on the lake surface. Because it is difficult to differentiate in practice between underestimation of rainfall and overestimation of evaporation, the choice of estimate is somewhat arbitrary. In the belief that variations from year to year would be small by comparison with variations in lake rainfall, the estimates of evaporation used by the Institute of Hydrology were based on monthly averages obtained by the Penman method for stations around the lake. The annual total was 1,858 mm.

The rainfall over the lake surface provides the major part, on average about 85% of the input to the lake water balance. It is not easy to estimate this rainfall as the only regular measurements have been made at stations around the lake perimeter. There are only eight stations with records from 1925 or earlier, and these records have been used by a number of investigators to estimate the rainfall input; the approach has the advantage of providing a reasonably homogeneous set of records of rainfall variations from year to year. The problem of estimation is made complex because evidence from the timing of rainfall incidence on the eastern and western shores, supported by some observations from rainfall stations on lake islands, suggests that rainfall over the lake itself is significantly higher than at the lakeside stations. The Institute of Hydrology used the lake itself to measure rainfall by a water balance approach; in 1993, direct

Nile Basin, Lakes, Figure 3 Kagera swamp below Rusumo Falls: (a) monthly inflows and outflows, 1970–1973; (b) deduced monthly water levels, 1970–1973. (From Sutcliffe and Parks, 1999, Fig. 3.4.)

comparison between the lakeside rainfall and net lake rainfall for calendar months in 1969–1978 suggested that they were linearly related, and this was used to derive a long rainfall series.

This rainfall series for the period 1956–1978, together with inflow and outflow totals expressed as depths over the lake surface, are included in Table 1. Further details of the balance study are given in Sutcliffe and Parks (1999).

When these components of the water balance are used in an annual water balance to estimate the changes in lake level, and these estimates are compared with measured levels, the correspondence is close. This is illustrated in Figure 4 for the period 1956–1978, when the records are most complete. This period covers the period of the rise in the lake, and its background is illustrated by the statistics of Table 1. Although the tributary inflow is small compared with the rainfall input, the tributary flow is comparatively

much more variable than the rainfall, because the runoff coefficient itself varies with rainfall. Because the average lake rainfall and evaporation are similar in total, the lake is very sensitive to an increase in tributary inflow. The doubling of the lake outflow after 1964 has had a significant effect on the lakes below Lake Victoria, but more significantly in the Bahr el Jebel wetlands of the southern Sudan where the swamps areas trebled in size.

It is worth noting that although the rise in lake level in 1961–1964 is unique within the period of measured lake levels from 1896, there is evidence from downstream flows and from early travelers (Tate et al., 2001) that the level was as high in 1878 and about 1892 though the return to lower levels was more rapid than after 1964. There is evidence from the southern Sudan that there was a period of high floods on the Bahr el Jebel after 1878, so the 1961–1964 event was not unique.

Lake Kyoga

The outflows from Lake Victoria, which reflect the bimodal nature of the rainfall on the lake itself (March–May and October–December) and on the tributary catchment, are attenuated by the large lake storage so that the seasonal peak monthly outflow in June is only about 15% higher than the low flow in November. The river, here called the Victoria Nile, flows for about 100 km below Jinja and reaches

Nile Basin, Lakes, Table 1 Annual water balance of Lake Victoria, 1956–1978 (After Sutcliffe and Parks, 1999, Table 3.3)

Year	Rainfall, mm	Inflow, mm	Outflow, mm	Level, m
1956	1,787	288	293	10.91
1957	1,727	270	300	11.02

Coefficient of variation (%)	9.7	30.1	28.4	

Lake Kyoga, which has the shape of a submerged river valley in an area of subdued relief. The lake is shallow, with a depth of about 3–5 m at its western end and shallower in its upstream arms. There is some uncertainty about the area of the lake and adjoining swamp, but a recent WMO estimate of 4,700 km² is reasonable.

Because the available records are largely confined to inflows and outflows in the main river, it is not easy to determine a complete water balance as local inflow is not measured consistently. Inflows in the main Nile are similar to outflows at Jinja, while lake outflows are available at Masindi Port from 1912, and more accurate measurements are available at Kamdini from 1940 to 1977 (Sutcliffe and Parks, 1999, Chapter 4). Local rainfall on the lake is about 1,300 mm compared with evaporation of about 1,600 mm. Comparison of inflows and outflows reveals that during the comparatively dry conditions before 1961, the channel inflows slightly exceeded outflows, suggesting that lake evaporation exceeded rainfall and local inflow. By contrast, after 1964, the outflows exceeded inflows, showing that local runoff and rainfall had increased to exceed lake evaporation. The annual net basin supply for the period 1940–1977 has been shown to be reasonably correlated with annual rainfall around the lake.

Lake Albert

Below Lake Kyoga, the course of the main river, here known as the Kyoga Nile, is influenced by the geological history of the region. The river turns up a former tributary of the Kafu below Masindi Port and then turns west to enter the Rift Valley and Lake Albert through the Murchison Falls. This lake is flanked by the Rift Valley escarpment on the east and by steep mountains on the western or Congo side of the lake. The lake is rectangular in shape with steep shores on its flanks and has an area of 5,300 km²; it reaches a depth of 50 m.

Lake levels have been measured at Butiaba, the port on the lake, from 1904 to 1981 (Figure 5). As would be expected, these records reflect the pattern of Lake Victoria

Nile Basin, Lakes, Figure 4 Lake Victoria annual water balance, 1956–1978. (From Sutcliffe and Parks 1999, Fig. 3.9.)

levels upstream, with the rise of 1917 being exceeded by the levels of 1961–1964; the fall in levels after 1964 has been more rapid than at Jinja. The water balance of Lake Albert is less well documented than the other lakes. The main inflow is carried by the main river, the Kyoga Nile, and has been measured at Kamdini for the period 1940–1977. A second tributary, the Semliki, drains a basin of 30,500 km² south of Lake Albert which includes the Ruwenzori Mountains and Lakes Edward and George; the flows of the Semliki have been measured at Bweramule from 1940 to 1978 at an average annual rate of 4.6 km³. There is additional local runoff estimated at 2.5 km³ from other streams which flow into Lake Albert.

Although attempts have been made to measure or estimate the immediate outflow from Lake Albert, the only long-term measurements below the lake have been carried out at Mongalla on the Bahr el Jebel. Flows at this site, where the main river enters the wetlands of the Sudd, have been measured from 1905 to 1983 with an annual average of 33.3 km³; however, these flows include the flow of the seasonal torrents which enter the river between Lake Albert and Mongalla; their estimated long-term annual measurement is 4.4 km³. Because the only long-term rainfall station near Lake Albert has been at Butiaba, with an average annual total of about 800 mm, there is likely to be a net evaporation loss from the lake. Although some of the elements of the lake water balance have had to be estimated, there is evidence (Sutcliffe and Parks, 1999) that the annual lake outflow and storage change minus inflow is related to Butiaba rainfall.

Balance of Lakes Victoria, Kyoga, and Albert

The overall balance of the successive lakes is indicated in Figure 6 where lake rainfall and local inflow are compared with lake evaporation and lake outflow for the years 1951–1960 (1956–1960 for Lake Victoria) and 1966–1975. Each component is estimated by various means

and is expressed as an annual volume (km³); the balance is not precise and discrepancies are partly explained by storage change. The figures demonstrate the importance of lake rainfall and evaporation in the case of Lake Victoria, and also the increased inflow in the later period. The dominance of Nile inflow and outflow in the balances of the lower lakes is apparent. The doubling of the overall outflow between the two periods is important, especially its effect on the Bahr el Jebel wetlands downstream. This increase was largely generated in the Lake Victoria basin, though the lower lake basins also contributed.

Lakes Edward and George

There are two further lakes in the Semliki basin above Lake Albert. Lake Edward (2,200 km²) and Lake George (300 km²) are connected by the Kazinga channel and receive inflow from the western channel of the Katonga and from a mountainous catchment. However, the main hydrological information is confined to lake levels on Lake Edward, measured from 1942 to 1978, which reveal a similar pattern to the other East African lakes, with a similar rise in 1961–1964 but a more rapid subsequent fall, and the flows of the Semliki measured above Lake Albert. These records do not permit a detailed water balance.

Lake Tana

The remaining major lake in the Nile basin is Lake Tana, which is situated at the upstream limit of the Blue Nile in Ethiopia. It was studied (Grabham and Black, 1925) as a possible site for reservoir storage and has been developed for hydroelectric power production. The lake has a surface area of about 3,000 km² at an elevation of 1,800 m. The basin draining to the lake is 13,750 km² and rises to nearly 4,000 m. The lake has many tributaries, with high and perennial, and highly seasonal runoff. The level range of the lake during this period was about 2 m; the shoreline contains a number of swamps dominated by *Cyperus papyrus*.

Nile Basin, Lakes, Figure 5 Lake Albert monthly levels, 1904–1983. (From Sutcliffe and Parks, 1999, Fig. 4.10.)

Nile Basin, Lakes, Figure 6 Schematic balance of Lakes Victoria, Kyoga, and Albert, $\text{km}^3 \text{ year}^{-1}$. (After Sutcliffe and Parks, 1999, Fig. 4.16.)

The Blue Nile leaves the lake through a series of cataracts, including the Tississat Falls with a drop of 50 m. Hydrological observations were carried out by the Egyptian authorities between 1920 and 1933; the mean annual outflow was 3.8 km^3 , or 7.8% of the long-term flow of the Blue Nile at Roseires.

NORTH DELTA LAKES, EGYPT

Mohamed I. Balah
Suez Canal University, Port Said, Egypt

Introduction

The Egyptian Mediterranean coast has five brackish lakes (Northern Delta lakes) which are situated along the Nile delta coast and to the east of the Suez Canal. These lakes are, from west to east, Maryut, Idku, Burullus, Manzala, and Bardawil (Figure 1). All except Lake Maryut are directly connected to the sea.

Lake Manzala is the largest of them with a total area of about 90,000 feddans and the depth rarely exceeds 2 m. Lake Burullus is the second largest Delta lake, with total area of about 70,000 fed. and an average depth of 1.2 m. Lake Idku is situated approximately 35 km east of Alexandria. It is a shallow eutrophic lake rarely exceeding 1.5 m in depth. Lake Mariut is the smallest of the Delta lakes, occupying about 17,000 fed. It is actually isolated from the open sea. The depth ranges from 0.6 to 2.7 m.

The Northern Delta lakes provide a rich and vital habitat for estuarine and marine fish and their regeneration and have always been major areas of fish production in Egypt, where more than 75% of Egyptian lakes production was harvested from them (Mehanna, 2008). Also, they are internationally important sites for wintering water birds, providing valuable habitat for several hundred thousand

birds. In recent years, these lakes are facing many challenges, leading to the depletion of fish production from them (Figure 2).

Degradation, habitat loss, filling up, and drought which lead to decreasing the area of all Delta lakes by more than 70% of their origin areas. Delta lakes are the most polluted areas in Egypt. They receive great amounts of industrial, municipal, and agricultural wastewater without treatment. Spread of aquatic plants which covered large areas from these lakes. Over-fishing, illegal fishing practices, and illegal harvesting of fish fry. The blockage of Boughazes (the connections with open sea). High levels of eutrophication resulting from the increased nutrient influx from agricultural drains carrying large amount of washed and leached fertilizers and pesticides.

The present research shows the main features of the five Northern Delta Lakes (Maryut, Idku, Burullus, Manzala, and Bardawil).

Burullus Lake

Burullus is the second largest lake of the Nile delta coastal lakes. It is connected to the sea at its northeastern edge through the Burullus inlet, which is about 250 m wide and 5 m deep, (Figure 3). It is about 53 km long, 13 km wide, and has water depths ranging from 0.5 to 2.5 m (Frihy and Dewidar, 1993) (Figure 4). The northern border is separated from the Mediterranean Sea by a strip of land covered with sand bars and dunes. Seven drains and freshwater canals are connected to its eastern, southern, and

North Delta Lakes, Egypt, Figure 1 Northern Delta Lakes, Egypt.

North Delta Lakes, Egypt, Figure 2 Fisheries resources of Egypt during the 1980 compared with those of the last 8 years. (After Mehanna, 2008.)

North Delta Lakes, Egypt, Figure 3 Burullus Lake, Egypt.

western shores. The lake barriers are sandy and range from 0.4 to 5.5 km in width. They are generally <1.5 m above mean sea level, with beach face slopes ranging between 5° and 13°. Low relief backshore and fore dunes characterize the western barrier. The eastern barrier is narrow and backed by barchans coastal dunes. These dunes encroach landward onto a cultivated coastal flat. Water is discharged into the lake through a series of seven land drains. The estuarine water of the Rosetta mouth of the Nile River is also connected to the lake water through the Brimbal Canal. These water sources and other (rainfall and seepage of underground water) cause the rise in the lake level, inducing a lake sea current (Saad, 1990).

Several studies have been carried out on the different aspects of the lake ecology (El Sabrouti, 1984; Saad,

1988; Abdel Moneim et al., 1990; Fatouh, 1990; Maiyza, et al., 1991; Shakweer et al., 1998). These results showed that the water quality of the lake has changed over time. These changes are related to human intervention and eutrophication processes. The bottom sediments of the lake are predominantly silty clay, with high organic content in parts and large areas of shelly to silty, muddy sand (Coutlier and Stanley, 1987). Approximately 75 islands are scattered in Burullus Lake with varying surface areas, and they comprise a variety of habitat types. Several studies indicated that the size and shape of Burullus Lake has changed due to a shrinking, resulting in increase in island size (Khedr, 1999).

The spatial distribution of sand and organic matter values is consistent with the results of Coutlier and Stanley

North Delta Lakes, Egypt, Figure 4 Bathymetry map of Burullus Lake. (After, Frihy and Dewidar, 1993.)

(1987) which indicated that the texture of bottom sediments is modified from silty clay, with high organic content in parts and large areas of shelly to silty muddy sand (Figures 5 and 6).

The salinity values are higher than 5,000 mg/l for most of the lake parts. At the western and southern part of the lake, the salinity levels are lower than 1,000 mg/l (Figure 7). The main causes are the lake's nearness to the freshwater resource from Rosetta branch of the Nile River (Brimbal Canal) and the inflow of drainage water from southern drains.

According to Fanos (1992), the tide at El-Burullus headland is estimated as the difference between the mean high water level (33 cm) and the mean low water level (18 cm). Fanos (1992) considered the difference (15 cm) as small and concluded that the tidal effect is small. Accordingly, the tidal effect has been neglected. El-Shinnawy (2003), Rainfall data recorded at Al-Burullus lighthouse (31°36'N, 31°05'E) for a period of 81 years (1912–1992) has been collected and examined. Monthly records of rainfall data have been treated and statistically analyzed. Mean monthly values have been estimated and illustrated in Figure 8. The mean annual depth of rainfall is 187.37 mm. This depth of water provides the wetland with a mean annual volume of about 77.35 million cubic meters.

Evaporation measurements at adjacent stations in Port Said and Alexandria localities have been collected and analyzed. An average value for daily and monthly evaporation at the study area in each month was estimated as presented in Table 1.

Bardawil Lake

Bardawil Lagoon is located at the southeastern Mediterranean coast at 31°09'N, 33°08'E (Figure 9). It is an oasis for migrating birds as well as a Zaranik protected area (Anonymous, 2005), an important source for economical fish and salt production (Abd Elrazek et al., 2006; El Shaer, 2008), and a high diversity of habitat for wildlife (Touliabah et al., 2002). The lagoon is nearly clear and it is the least polluted in the entire Mediterranean region (Arvanitidis et al., 2009). The Bardawil lagoon represents a transitional zone between land and sea and it is separated from the Mediterranean Sea along most of its length by a long and narrow sand bar. It is connected to the sea via three narrow artificial inlets (Figure 10). Two of them are man made (western and eastern inlets), while the third one has been naturally closed (El-Shabrawy, 2006). The lagoon extends along the coast, and so it has a micro tidal regime. The Mediterranean Sea tides govern water exchange in the lagoon and have a mean tidal excursion of 25 cm during neap tides and about 35 cm during spring tides (Moursy, 1994).

Bardawil lagoon suffers from many problems, which might lead to environment degradation, shortage in fish catch, and substantial changes in its ecosystem. Drying up of some areas inside the lagoon and subsequently loss of its biological and economic values is due to the frequent changes in inlets' form and dimension. An extensive salt production system (constructed in the eastern part) leads to considerable ecological changes.

There are many investments around the lagoon, like tourism developments. There is a large-scale agriculture

North Delta Lakes, Egypt, Figure 5 Distribution of sand% for Burullus. (After, Dewidar et al., 2005.)

reclamation project in North Sinai near the lagoon; the inflow of freshwater from the new reclamation lands will change the lagoon from a saline to brackish lagoon, leading to the deterioration of water quality (Mageed, 2006); otherwise, Bardawil Lagoon development, including urbanization and lagoon engineering such as artificial inlets, promotes some undesirable changes in its system. Radwan et al. (2009) carried out a study to evaluate Bardawil Lagoon from a physical limnology point of view, through investigation of its climate, bathymetry and morphometrical features, and monthly and annual changes in salinity.

Bardawil has shallow water with irregular bottom topography. Figure 11 shows the lowest water depth (0.3 m) and the highest (6.5 m) recorded at the extreme eastern region (Zaranik area) and inside the inlets, respectively. The average water depth inside Bardawil Lagoon is around 1.21 m. The Lake bottom is composed of sand and silt (Levy, 1971).

Air and water temperatures of Bardawil Lagoon are low in winter and high in summer (13.7–27.0°C and 13.9–24.6°C, respectively). Winds blow from all directions, but most abundantly from the north most of the time. The recorded wind speed shows great variability from a month to another ranging between 4.5 and 6.3 m/s. The relative humidity varied between 48.5% and 57.1%.

Evaporation rate is low in winter and high in summer (3.23–6.0 mm/day), (Figure 12).

Figure 13 illustrates spatial and temporal water salinity distributions inside the Lagoon. From the salinity results it could be concluded that there is a high fluctuation in the salinity range, the lowest value is 38.3‰ and the highest is 71.1‰.

Lake Manzalah

Lake Manzalah is almost rectangular in shape with a long axis running from the northwest to the southeast (Figure 14). It is connected to the Mediterranean Sea through the main opening at Al-Gameel region, west of Port Said, and it is connected with the Suez Canal through a small canal at Al-Gabouty near Port Said. Highly productive freshwaters of the Nile enrich the Lake through three canals originating from the Damietta Branch: Al-Enania, Al-Rotma, and Al-Sufara canals. The Lake is enriched by drainage water transported by five main drains which are connected to the Lake at the south and southeastern borders (Figure 15). These drains are Al-Serw, Al-Gamaliah, Bahr Hadus, Ramsis, and Bahr-Bagar. Malati (1960) mentioned 1,022 islets with a total area of 3,137 feddans. These islets divide the Lake into about 30 basins. Most of these islets are inhabited by fishermen and farmers.

North Delta Lakes, Egypt, Figure 6 Distribution of organic matter% for Burullus. (After, Dewidar et al., [2005](#).)

North Delta Lakes, Egypt, Figure 7 Salinity distribution for Burullus Lake. (After, Dewidar et al., [2005](#).)

At the beginning of the twentieth century, the surface area of the Lake was about 420,000 feddans. Because of the continuous processes of land reclamation for agriculture, the area has gradually decreased reaching in 1980 to about 200,000 feddans (Macleren, 1981). In fact, Lake Manzalah is affected by various external factors, the most important of which is the progressive increasing of industrial and agricultural wastewater discharge.

The bottom of Lake Manzalah is covered with silty clay and sandy silty clay in the southern part. The western and southwestern regions have bottoms covered with silty clay. The central regions of the Lake are mainly covered with clayed sand (El-Wakeel and Wahby, 1970b). Further to the northeast, the Lake bottom is composed of silty clay.

The Lake bottom is contaminated with different accumulations of lamellibranches. Three regions constituting the bulk of Lake Manzalah were described by El-Wakeel and Wahby (1970a) as follows: (a) Southeastern region, which receives its water from Hadus and Bahr El-Bagar drains; (b) the second region extending along the route connecting Mataria to Port Said; and (c) the third region occupying the western side of the Lake, which receives freshwater from the Sufara, Ratma, and Enaniya canals. This area is affected also by the water coming from Faraskour Barrage. Guerguess (1979) found in Lake Manzalah that the minimum pH values were recorded at this area where it varied between 7.0 and 7.80 with an average of 7.46. He attributed the decrease of pH values

to the high rates of wastewater discharge from three drains at this polluted region.

The direction and speed of blowing winds as well as the chemical properties of wastes discharged into the Lake are the most important factors affecting the chemistry of Lake Manzalah waters. The strong northern winds blowing steadily from March to September pile up the sea water along the coast resulting in rising sea level and may contribute in transporting the sea water into the Lake. The directions and speeds of winds blowing on Lake Manzalah during the whole year can be briefly indicated as follows:

During *winter* season the winds at Port Said blow mostly from NE, NW, and SW, with velocities from 1 to 21 knots, mostly from 4 to 10 knots

During *spring* season the winds blow mostly from NW, less from SE and S, with velocities ranging from 1 to 21 knots, moderately from 4 to 6 knots.

The *summer* season is characterized by calm winds (NW), with velocities from 1 to 16 knots, moderately from 1 to 3 knots NW winds.

During *autumn*, the winds blow mostly from NW and NE, with velocities ranging from 1 to 16 knots, and moderately from 4 to 6 knots.

Due to the shallowness of Lake Manzalah together with the common mixing of water by wind, the thermal stratification was difficult to be established in the water body of the Lake (Wahby et al., 1972). The recorded water temperature at the various sampling stations are given in Tables 1 to 6 and graphically shown in Figure 16.

It can be observed from the data given that:

- The minimum water temperature was recorded during January when water temperature ranged from 11.0°C to 13.0°C, this agrees with El-Araby (1990)
- The maximum water temperature was recorded during July ranging between 27.0°C and 30.0°C with an average of 29.0°C, as recorded by El-Araby (1990)
- The water temperature started to increase gradually from February to reach the maximum in July where it began to decrease gradually reaching its minimum in January
- The difference in water temperature did not exhibit large values from one station to another

Beside temperature effect on the chemical and physical characteristics of the environment, it has a great effect on the vital activities of the living organisms. Temperature influences the total standing crop of phytoplankton where it decreases during winter and regains its maximum during spring and summer. Dissolved oxygen as well is influenced by temperature, since reverse correlation exists

between dissolved oxygen and temperature (Saad, 1987). Prepas and Trew (1983) found that temperature influences on phosphorus release increase in summer. In addition, it is well known that fish is sensitive to temperature variations. The minimum water temperature was recorded with an average of 12.35°C in January while the maximum was 29.14°C in July.

The evaporation accelerated by the high summer temperature as well as the rain water are other factors influencing the total dissolved solids (TDS) in the lake.

The effect of increasing human activities, mainly industrial, agricultural, and mariculture carried out at the areas adjacent to Lake Manzalah, on the Salinity of N.E. area, was observed. The values of salinity and TDS during 1967 (Youssef, 1967, 1975, El-Araby, 1990; Shakweer, 2005) are given in Table 2. The data given indicate that

El-Gamil area exhibits steady decrease of water salinity where its average value decreased from 17.24‰ to 5.37‰ in 1975 and to 2.53 g l⁻¹ in 2001. This region, though was characterized by high rates of primary and fish production, is suffering now from drastic water pollution and decreased rates of fish production.

Maryut Lake

Lake Maryut is the westernmost of the northern delta wetlands (31°07'N/29°53'E), although its history and origin are different (Figure 17). Formerly, the lake was fairly large, but late in the nineteenth century the western half was cut off by a railway embankment and transformed into an extensive salina, now known as Malahet Maryut, which is seasonally flooded (usually during winter). Today, the remaining part of this lake is made up of several

North Delta Lakes, Egypt, Figure 13 The spatial and monthly variation of the water salinity in Bardawil Lagoon. (After, Radwan et al., 2009.)

fragments, dissected by roads and embankments, and lies practically within the boundaries of greater Alexandria and its sprawling suburbs.

What remains of the lake proper is brackish, receiving agricultural drainage water through several drains (the most important of these is the Qala Drain), as well as large quantities of municipal and industrial effluent from the city of Alexandria. The lake has no direct connection with the Mediterranean, and it is maintained at a level of c. 2.8 m below sea-level by a pumping station at El Max. Much of the lake shore is fringed by extensive *Typha/Phragmites* marshes. The lake still supports a fishery, with *Tilapia* sp. making up most of the production.

By the end of the nineteenth century, the development of irrigation systems of the adjacent fields made Lake Mariut an intermediate water body to receive the excess of water from the irrigation channels. Then the water was pumped out to the Alexandria Bay. Lake Mariut, for a long time, represents a source of fish production in Egypt. Currently, some parts of the lake are used in aquaculture activities. The *Tilapia* sp. is of considerable importance in fisheries of Lake Mariut as it represents about 90% of the total catch in the lake (Bakhoum, 1994).

Nowadays the lake occupies around 250 km² due to intense land reclamation for urban and agricultural purposes. The life of Lake inhabitants continues to be carried on in much the same way as in ancient times, but now the reed masses cover more than 50% of the lake and fisheries richness has declined both in volume of catches and in fish quality. The Lake is artificially subdivided into four basins

(Figure 18); Main Basin, Aquaculture Basin, Southwest Basin, and Southeast Basin – Main Basin: 25 km² (6,000 feddans), Fisheries Basin: 4.2 km² (1,000 feddans), Northwest Basin: 12.5 km² (3,000 feddans), Southwest Basin: 31.5 km² (7,000 feddans).

Unfortunately, Lake Mariut suffers from almost all possible environmental problems and to quite an extreme degree. Land filling for building houses, infrastructures, and agriculture has reduced the area of the Lake from 700 km² to the present 250 km². These three human activities have critical impacts on the remaining area of the Lake. Pollutants load has been estimated at 122.6 t/day for sanitary drainage, 180 t/day from industries, and up to 6 million m³/day of agricultural wastewaters. All these inputs introduce in the Lake huge amounts of inorganic and organic toxic substances, such as different forms of nitrogen, phosphorus, heavy metals, pesticides, and pathogens. Urban expansion from the densely populated Alexandria and the uncontrolled deposition of solid waste complete a very complicated and distressing environmental panorama for Lake Mariut making it the most polluted one in Egypt. The Main Basin, the main object of this assessment, which covers an area of about 25 km², has been suffering from high levels of pollution. Currently, the main sources of pollution in this part of the Lake are caused by:

- (a) The West Treatment Plant Outfall, which discharges about 200,000–300,000 m³/day of settled sewage into the lake

North Delta Lakes, Egypt, Figure 14 Lake Manzalah, Egypt.

- (b) El Qallaa Drain Outfall, which discharge about 400,000 m³/day of agricultural wastewater and sewage into the lake after primary treatment (El Sharkawi, 1999; Kassim, 2005); in general, El Qallaa Drain is considered the major source of pollution in the lake (Samman et al., 1988)

In addition to these two sources of pollution, previously for a long period, Gheit El Enab Outfall was discharging about 25,000–35,000 m³/day of raw sewage and some industrial wastewater into the lake. Since the early 1990s, such quantity of wastewater has been directed to the West Treatment Plant (El Sharkawi, 1999). Also, about 25,000–30,000 m³/day of industrial wastewater used to be discharged into the Main Basin of the lake from the Moharam Bey Industrial Complex. Such industrial wastewater has high BOD, COD, oil, and suspended solids (Table 3).

Lake Mariut Physicochemical Descriptors (Water)

Moreover, the shores of Lake Mareotis embraced major production centers for different industries such as

glass, pottery, and wine, which contributed significantly to the economy of Alexandria and of Egypt as a whole. To date, however, Lake Mareotis has been a much underrated resource particularly with respect to its economic relation to Graeco-Roman Alexandria. Moreover, many archaeological sites located along the shores are endangered by modern urban development and various industrial and agricultural activities. Lake Mareotis, precursor of the present Maryut Lake, represented one of the most distinctive geomorphological features in the north-west coast of Egypt during the Holocene period. It was, and still is, quite unique compared to other lakes on the Egyptian north coast, which were formed as a result of the sea inundating the north coast of the Nile Delta. In antiquity, Lake Mareotis was formed solely by the Nile, which fed the lake through a network of canals that branched off the river's defunct Canopic Branch and approached the lake from the south and the east (Figure 19).

Moreover, it was connected to the sea at Alexandria through a navigable canal that debouched at the city's western harbor. Accordingly, besides being a freshwater

lake, Mareotis also gave access to the Nile and hence to the whole of Egypt.

Historical, archaeological, and geomorphological evidence indicate that Lake Mareotis consisted of two

interlinked parts: the main basin of the lake, which extended for 40–50 km south of Alexandria, and a narrow arm, which was about 3 km wide and extended west of Alexandria for about 40 km. However, it is evident that Lake Mareotis has undergone dramatic changes during the past two millennia, which significantly affected its size and nature. During the fifth century A.D., the Canopic Branch started silting up and it became defunct by the twelfth century A.D. Accordingly, Lake Mareotis lost its connection to the Nile, and the once navigable freshwater lake became a closed lagoon with no constant supply of water. Due to increasing evaporation, the size of the lagoon decreased significantly and by the end of the eighteenth century Mareotis was almost dry, except in the rainy seasons. Lake Mareotis remained dry for almost 700 years until it was intentionally flooded with seawater twice in the early nineteenth century, as strategic actions, ending forever its life as a freshwater lake (Figure 20).

However, once again, Lake Mareotis started drying up due to increasing evaporation until most of its basin became dry arable land. It was not until the early twentieth century, when the major irrigation projects in the western Delta were established, that the depression started receiving agricultural runoff and irrigation water carried by a number of canals and drains, filling the depression and creating the present Maryut Lake.

At present, Maryut Lake is a body of shallow brackish water that occupies about 17% of its original size. It consists of two sections separated by a number of causeways and canals. The main body of the lake is nearly rectangular in shape, with its northern coast extending for about 20 km, while its eastern coast is about 12 km long. It has also been divided into many subbasins, which are used

North Delta Lakes, Egypt, Figure 15 Map of Lake Manzalah showing the main drains and location of the sampling stations. The main basins are: 1, Bahr Genka; 2, Bahr Lagan; 3, Bahr Bashtir; 4, Bahr Kassab; 5, Bahr El-Gainil; 6, Bahr Deshdee; 7, Bahr Abwat; 8, Bahr Kurumulls; 9, Bahr El-Zarka (After, Shakweer, 2005.)

for industrial and agricultural purposes. Moreover, its shores are subject to continuous irrigation, drainage, and reclamation projects, which make it constantly changing and unstable. The second part of the lake takes the shape

of a narrow arm that extends westward for about 40 km west of Alexandria. It is about 3 km wide and is delimited from the north and south by two coastal ridges. This western arm also contains an elongated Island which is about 4 km long and 500 m wide. Much evidence indicate that the western extremities of Lake Mareotis and its associated Island reflect the extant remains of the original lake that has not been subject to dramatic changes since antiquity. Since the lake receives its water from groundwater seepage, agriculture runoff, and rainfall, its water level fluctuates widely according to the seasons. In the rainy winter season, the water precipitates through the ground to raise the water level of the subbasin, while in the dry summer season, high rates of evaporation contribute to lowering the water level.

Idku Lake

Idku lagoon is the third largest coastal water body in the Nile delta. It is located in the northwestern part of the delta ($31^{\circ}12' - 31^{\circ}16'N / 30^{\circ}08' - 30^{\circ}18'E$) (Figure 21). The lagoon margin is essentially straight along its northern border; the eastern margin is bounded by Idku drain. The only connection of the lagoon with the Mediterranean Sea is the inlet Boughaz El Maadyah. The depth of the

Idku lagoon ranges from 0.1 to 1.5 m. Lagoon waters are brackish, with freshwater discharging mainly from the Idku drain. This large drain, a branch of El Mahmudiya canal, collects drainage water from the Beheirah Province watershed (Saad, 1976).

Three main drains discharge into the lake, while Buoghaz El Maadyah provides a connection with the sea. The water in the lake is mainly fresh, but increases in salinity toward the Buoghaz and during the summer. Most of the lake margins are covered with dense growths of Typha and Phragmites, which cover about 50% of the lake's area. Saltmarshes, salinas, and high dunes, as well as some orchards, are found on the sandbar separating the lake from the Mediterranean. Lake Idku supports a fishery of moderate importance.

Lake Idku suffers from the same ailments that affect other delta wetlands: drainage and land-claim, pollution, disturbance, water bird catching, etc. Habitat loss through

North Delta Lakes, Egypt, Figure 19 The extent of Lake Mareotis in antiquity and at present. (Lake Mareotis Research Project, 2004.)

North Delta Lakes, Egypt, Figure 21 Lake Idku, Egypt.

land-claim is certainly the most serious of these threats. Lake Idku has been reduced to less than half its original size. Sewage and industrial wastes, discharged into the sea from the industrial complex along the Abu Qir coast (Figure 22) via El Tabia pumping station, west of El Maadyah, may at times enter the lagoon through the inlet at El Maadyah (Saad, 1978a). The wastes supplement those transported by Idku drain and other channels flowing into the lagoon.

Numerous studies have considered the chemical and biological aspects of Idku lagoon (Saad and Ezzat, 1972; Saad, 1976, 1978a, b; Banoub, 1979, 1983). Idku lagoon is characterized by a marked variation in salinity (Saad, 1978a). This leads to its special feature of well-separated water masses that can often show concomitant phenomena in their biological and chemical characteristics. Domestic, agricultural, and industrial sewage contamination of the lagoon water is the most dangerous aspect since it results in high loads of allochthonous organic matter and nutrients, which enhance the growth of microbial mass as well as phytoplankton production. In addition, the introduced sewage may bring high numbers of microorganisms such as the pathogenic coliforms that might threaten aquatic plants and animals and also present a great hazard of public health.

General: This shallow brackish lake contains a number of islands and is situated 15 km SW of the mouth of the Rosetta branch of the Nile. It is 16 km long, has a maximum width of 10 km, and is separated from the sea by a narrow sand barrier. An extensive reed swamp at the eastern side has been partially reclaimed in recent years.

Hydrology and Water Quality: Water is received by drainage of the surrounding delta lands and exchange with the sea occurs through the Boughaz el Maadyah, with inflow from the sea occurring principally in winter. The lake is usually well oxygenated, and water temperatures range from 15°C to 29°C. Chloride ion concentrations range from 0.5 to 23 mg/l and total dissolved solids from 1,000 to 45,000 mg/l.

Flora and Fauna: The flora and fauna are much as described in the regional introduction. The lake supports *Ceratophyllum demersum* and dense mats of *Eichhornia crassipes*, with *Potamogeton crispus* and *Potamogeton pectinatus* in the most saline areas. It is eutrophic and highly productive. The eastern marshes are dominated by *Phragmites australis*. European animals such as *Lutra lutra* occur here.

Human Impact and Utilization: There is a flourishing fishery in which *Oreochromis* spp. account for 82% of the catch, *Anguilla anguilla* for 10% and *Mugil* spp. for 6%.

NUTRIENT BALANCE, LIGHT, AND PRIMARY PRODUCTION

Thomas Hellström
Thellva HB, Dalarö, Sweden

Description

Primary production, which occurs in plants (from algae to trees), converts inorganic matter to organic matter. The driving force is sunlight. Organic matter contains energy. Prerequisites except sunlight are that nutrients and water are available. Main nutrients are phosphorus, nitrogen, and carbon dioxide.

Primary production is the input of organic matter and energy, which drives biology in all other trophic levels. Exceptions may be very small lakes in forests, where organic matter from forest litter can be an input of importance. Main primary production is normally due to growth

of microalgae. In shallow water, macrophytes may sometimes dominate the production. For algal growth, nutrients and energy are needed. Primary production produces energy-rich bonds as a result of photosynthesis. A simplified stoichiometry of the reaction looks like:

More simplified (less properly) the reaction is sometimes described as:

The production will go on until something limits. A number of nutrients and trace elements are needed. It is either sunlight or some nutrient or combination of nutrients that limits. During winter in those regions where there is a winter, sunlight is the limit. Otherwise most often phosphorus or nitrogen or both are limiting. As seen from the stoichiometry, nitrogen and phosphorus are needed in the molar ratio 16/1 (N/P). Algal production also causes an increase in oxygen and pH. Increase in pH does not occur if ammonium (NH_4^+) is the nitrogen source.

Respiration is the reaction backward. This is carried out by bacteria and other predators. Respiration also causes a release of nutrients, which can be reused. Some of the algal biomass will reach bottom sediments, and release of those nutrients (mainly phosphorus) cannot be reused immediately. Some will leach out from sediments and can be used later when it reaches productive upper layers, i.e., where sunlight is enough to drive photosynthesis.

When a system is running out of nitrogen (mainly nitrate, nitrite, and ammonium), a surplus of phosphorus will develop. Then cyanobacteria (also called blue-green algae) will start to grow. These organisms, which like bacteria are prokaryotic in cell structure, do not need nitrogen in the form of nitrate, nitrite, or ammonium for their growth. They can use dissolved nitrogen gas (N_2) directly. It is called N-fixation. The limit for cyanobacteria will be phosphorus. Through respiration (destruction), the biomass of cyanobacteria will feed the system with nitrogen.

Another limit factor can be short water detention time in the local system. This means that the algae are washed out before they could balance the system.

Sunlight during summer is more than enough near the surface. Sunlight can often limit photosynthesis at the surface because of too high intensity. Due to adsorption of sunlight intensity, it will decrease with depth and cause a maximum of production until it will fade out and stop photosynthesis at about 1% of the surface intensity. Adsorption of sunlight is mainly caused by particles including algae but will also decrease due to scattering

by water itself. When the algal biomass is high, the production can be strongly limited by self-shading.

Nutrients will increase due to various emissions and leaching from agricultural land. Nitrogen can also be added through atmospheric deposition. Phosphorus input through atmospheric deposition is normally very low. Phosphorus content is naturally the lowest in mountainous regions of crystalline morphology and increases in lowlands of sedimentary rock deposits.

In regions of lower phosphorus levels, nitrogen is in abundance, which also means that there are almost no cyanobacteria.

When the nutrient levels (i.e., phosphorus) are at high levels, this usually means high productivity and high abundance of organic matter. Organic matter is a driving force for denitrification. Denitrification means that some bacteria use oxygen in nitrate in their process of destruction of organic matter and leave nitrogen as nitrogen gas (N_2). Therefore, a lack of nitrogen compared to phosphorus can emerge. Therefore, presence of N-fixing cyanobacteria is more common in more eutrophicated waters.

Eutrophication means increased nutrient levels. The degree of eutrophication is classified after phosphorus

levels or after chlorophyll a. Chlorophyll is the pigment in algal cells, which carry out the photosynthesis. From low levels too high water are classified to be: oligotrophic, mesotrophic, eutrophic, and super eutrophic. There exist many classification limits between the different eutrophication groups.

Introduction

Lake Okeechobee is a large (1,730 km²), shallow (mean depth 2.7 m) subtropical lake located at the center of the Kissimmee-Okeechobee-Everglades watershed of southern Florida (Figure 1). The present-day lake contains three distinct ecological zones (Figure 2: Havens and Gawlik, 2005): a deeper *pelagic zone* underlain by mud sediments with waters high in nutrients and resuspended sediments, a shallower *nearshore zone* underlain by sand and peat sediments with varying water quality and coverage of submerged aquatic vegetation, and a *littoral zone* of sand and peat that is lower in nutrients and supports a diverse emergent wetland plant community that provides critical foraging and breeding habitat for much of the lake's fauna. Direct rainfall, most of which falls during the summer wet season, contributes over half of the water entering the lake, with much of the remainder coming from the lake's major tributary, the Kissimmee River, to the north. Due to its large surface area and warm climate, roughly two thirds of the lake's water losses are due to evapotranspiration, with water releases to estuaries on Florida's east and west coast, agricultural lands, and the Florida Everglades accounting for the remainder. The lake is managed as a multipurpose resource that provides significant economic and environmental benefits to the region. It plays a central role in regional flood control and water supply for more than seven million people (U. S. Census Bureau, 2010). The lake is used heavily by

both resident and migratory water birds, including threatened and endangered species (Audubon of Florida, 2005), and contains an internationally recognized sports fishery that provides more than US \$17 million annually to the local economy (Bell, 2006).

Pre-settlement condition

The lake formed approximately 6,000 years BP in a large, shallow depression during a period of increasing rainfall and sea level rise following the last glaciation (Brooks, 1974). The depth of the lake increased in tandem with the accretion of deep peat soils in the sawgrass (*Cladium jamaicense*) wetlands of the Florida Everglades to the south, which formed a natural dam that had raised lake levels by 4–5 m by the late nineteenth century (Brooks, 1974). The Everglades also served as the sole natural outlet from the lake, which discharged large volumes of water seasonally as sheet flow across its broad southern shoreline. In addition to this direct connection to the Everglades, the pre-settlement lake was bordered on all other sides by a nearly continuous fringe of herbaceous and forested wetlands (Lodge, 2004).

Human modifications

Lake Okeechobee has undergone substantial changes during the past century as a result of human development of the southern Florida peninsula (Blake, 1980). A series of regional drainage projects began in the 1880s to control Lake Okeechobee overflows to the Everglades with the goal of draining large areas of the Everglades peatland for settlement and agriculture. Over several decades, the State of Florida funded construction of a network of canals to divert lake water eastward and southward to the Atlantic Ocean and westward to the Gulf of Mexico, thereby lowering lake water levels and reducing the volume of overland flow to the Everglades. Deficiencies in

Okeechobee, Lake, Florida, USA, Figure 1 Location and current surface-water features of the Kissimmee-Okeechobee-Everglades watershed. Watershed boundary is shown by the thick black line. Major water bodies and man-made canals are shown in blue. The direction of water flow through the watershed is generally north to south and from Lake Okeechobee to the Atlantic and Gulf coasts.

this drainage plan were revealed when major hurricanes passing over the lake in 1926 and 1928 generated large lake storm surges that flooded newly settled land to the south and caused significant loss of property and life. This disaster prompted federal actions during the 1930s that included improvements to existing drainage canals and the construction of a 134-km long levee extending around much of the lake to prevent future damage from storm surges. While this levee successfully contained another

major hurricane surge in 1947, other aspects of the regional flood-control system proved inadequate to prevent widespread flooding of agricultural and urban areas across southern Florida. In 1948, the federal government authorized additional public works that created the present-day water management system. The lake's levee was increased in height and length so that it surrounded nearly the entire lake, and the conveyance capacity of drainage canals from the lake to Atlantic and Gulf

Okeechobee, Lake, Florida, USA, Figure 2 Major ecological zones of Lake Okeechobee.

coast estuaries was increased to improve flood protection. The major tributary to the lake, the Kissimmee River, was channelized, and a series of water-control structures were installed or upgraded to better manage flows into and out of the lake. Pumping stations installed in the levee along the south end of the lake allowed excess water in agricultural lands to the south to be discharged back to the lake, a reversal of the natural direction of water flow. This practice, referred to as “backpumping,” allowed for improved flood control during the wet season and additional storage of water for use during the dry season.

Current management issues

By the middle of the twentieth century, much of the watershed surrounding the lake had been converted to agricultural uses, including a thriving sugar cane and winter vegetable industry on the reclaimed peatlands to the south and extensive ranchlands, dairy farms, and citrus groves to the north and west. Runoff from these developed lands increased nutrient loads to the lake as a result of fertilization, manure production, and oxidation of drained organic wetland soils, resulting in rapid eutrophication of the lake (Joyner, 1974). The historically phosphorus (P)-limited lake switched to a nitrogen-limited state as in-lake total P concentrations increased from pre-settlement levels (estimated to have been between 20–40 $\mu\text{g L}^{-1}$) to

around 100 $\mu\text{g L}^{-1}$ by the early 1980s (James et al., 1995). Biological responses to this enrichment have included periodic lake-wide cyanobacterial blooms, a shift in the benthic invertebrate fauna toward nutrient tolerant forms, and the spread of nuisance vegetation in the littoral zone (Havens et al., 1996; Johnson et al., 2007). Eutrophication has also been associated with an increase in the depth and coverage of nutrient-rich mud sediments across the lake bottom. This trend is likely due both to an increase in biological production in the lake in response to nutrient enrichment and to the diked state of the modern lake, which prevents the natural flushing of accumulated sediments during hurricanes that periodically pass over the region. These sediments are estimated to contribute half of the annual P load to the lake (Moore et al., 1998; Fisher et al., 2005) and are easily resuspended under windy conditions, resulting in high turbidity and nutrient release (Jin et al., 2011).

The ecology of Lake Okeechobee is also susceptible to changes in water-level (lake stage) management. The lake is operated within a “regulation schedule,” which dictates lake stages where water is released and stored during different times of the year (USACE, 2008). When lake stages are near the lower end of this schedule, turbid, high-nutrient water tends to be restricted to the pelagic zone and water depths, and chemistry in the nearshore and littoral zones are conducive to the maintenance of submerged and emergent vegetation and associated fish and wildlife (James and Havens, 2005). Lake stages near the upper end of the schedule promote mixing of water among lake zones, resulting in poorer water quality and reduced plant growth. Peak inflow volumes to the lake exceed current outflow capacity, resulting in rapid increases in lake stage in response to heavy rainfall (Abtew and Iricanin, 2008). Consequently, the lake experiences prolonged periods of excessively high lake stages that damage aquatic vegetation and produce conditions unfavorable for wildlife foraging and breeding. The lake’s regulation schedule was increased by 0.6 m in 1978 to allow for additional water storage to support increased water demands from a rapidly growing human population. This change further exacerbated ecological impacts due to high lake stages (Lake Okeechobee Littoral Zone Technical Group, 1988) and increased the frequency of high-volume water releases to the coastal estuaries during wet periods to maintain the integrity of the lake’s dike, resulting in salinity and nutrient impacts in these downstream water bodies (Doering et al., 2002).

The lake’s littoral zone has experienced invasions of several exotic plant species that have displaced native wetland vegetation and reduced the suitability of this important habitat for fish and wildlife species. *Melaleuca* (*Melaleuca quinquivera*), a fast growing tree species from Australia, was planted inside the lake’s levee during the 1930s and 1940s to provide erosion control and quickly spread into the littoral zone. This species forms dense monocultures that displace other plant communities and provide poor wildlife habitat. Vigorous control efforts

have essentially eradicated this species from the lake. Another highly invasive, monoculture-forming species, torpedograss (*Panicum repens*), was introduced to the watershed in the 1940s as a forage crop for cattle and had spread across 6,700 ha (nearly 20%) of the littoral zone by 1996 (Hanlon and Brady, 2005). This species is being contained using a combination of management practices including prescribed burning and aerial spraying of herbicides, but complete eradication is unlikely. The lake also contains several species of exotic fish, many of which were unintentionally released from the aquarium and aquaculture trades. The effect of these introduced species on native fisheries and other ecological functions in the lake remains unclear. Many of these species are of tropical origin and may succumb to low water temperature experienced in southern Florida lakes and wetlands during unusually cold winters, thereby preventing sustained population increases (Shaffland et al., 2008).

Several measures have been taken to reduce environmental pressures on Lake Okeechobee caused by contemporary regional land use and water management. A plan was adopted in 1979 to eliminate the backpumping of nutrient-rich agricultural drainage water into the lake for water supply. In 1987, the Florida Department of Environmental Protection (FDEP) enacted regulations requiring the use of best-available technologies to reduce P loads to the lake from dairy farms to the north, which were determined to export more P on a per acre basis than any other land use in the watershed. A more comprehensive watershed plan for reversing eutrophication was initiated to achieve the Lake Okeechobee total maximum daily load of 140 metric tons (mt) per year established by FDEP in 2001. This plan requires implementation of agricultural best management practices and chemical treatment of farm runoff as well as the construction of large-scale treatment wetlands to remove additional P from the lake's tributaries (McCormick et al., 2010). Declines in in-lake P concentrations in response to watershed load reductions are expected to be slowed by continued internal P loading from the large quantity of mud sediment that has accumulated in the lake. A comprehensive study of sediment management options was initiated in 2002 and concluded that dredging this material would require 30 years and over US \$1 billion (in 2002) to complete (Blasland Bouck and Lee Inc., 2003) and would not appreciably reduce internal P loading due to the continued presence of residual sediments (James and Pollman, 2011). Chemical treatment of these sediments was determined to be a more effective option for reducing sediment P loading, but the treatment cost (US \$500 million in 2002), and the expected short-term duration of its effectiveness (8–15 years) also rendered this solution impractical (Blasland Bouck and Lee Inc., 2003). Therefore, emphasis continues to be placed on watershed P-load reductions with the recognition that the recovery of the lake will be a long-term process.

Improved stage management in Lake Okeechobee is dependent upon state and federal programs designed to restore some of the water storage and flow features that existed in the pre-settlement watershed. The goals of these multi-decadal efforts are to: (1) reduce reliance on Lake Okeechobee for water storage and flood control by constructing additional storage basins within the watershed and (2) allow for more natural high-volume lake discharges southward to the Everglades, thereby restoring the hydrology of this wetland and reducing the need for excessive lake releases to the estuaries (Steinman et al., 2002). Interim steps providing incremental improvements in environmental conditions in the lake and downstream water bodies include modifications to the lake's regulation schedule and the release of lake water to the estuaries in a manner that better mimics natural flood pulses (USACE, 2008). Cooperative programs between government agencies, private landowners, and other stakeholders have also been explored to increase water storage on private lands throughout the watershed to dampen the extreme fluctuations in water levels and flows that characterize the current developed watershed (Bohlen et al., 2009).

ORIGIN OF LAKES AND THEIR PHYSICAL CHARACTERISTICS

Lars Håkanson

Department of Aquatic Sciences and Assessment
Institute for Water and Environment, Swedish University of Agricultural Sciences, Uppsala, Sweden

Definition

Catchment—The drainage basin which channels precipitation into a lake or single outflow.

Compartment—Any part of the environment or process which may conveniently be considered as a single entity. Used in developing mathematical models.

Compartment model—A model in which a series of compartments is used to represent the system of interest. Material can flow between the compartments. Differential or difference equations often are used to represent the rates of flow in the system.

Ecosystem—A community of organisms together with the environment they inhabit and with which they interact.

Epilimnion—The upper layer of lake water above the thermocline with a comparatively homogeneous temperature profile.

Hypolimnion—The layer of lake waters below the thermocline.

Morphometric—All the geometric characteristics relative to the shape of the basin (volume, surface, depth, etc.).

Residence time—The ratio of the volume of a water body to water discharge (corresponding to the theoretical time needed for a complete exchange of water).

Trophic level—The hierarchical level that an organism occupies in the food chain. The group of organisms that occupy the same level in the food chain.

Volume development—The ratio between the lake volume and the volume of a cone having the basis equal to the area of lake surface and the height equal to the maximum depth of the lake.

Classification schemes for lakes

The first classical work with a specific focus on the study of lake forms, describing their genesis and role in a broad limnological perspective, was *Limnological Methods* by Welch (1948). The source of morphometric data quantifying the size and form of lakes is the bathymetric map and such maps are today generally derived from echosounding, a technique that became more widely used after 1948. Most modern textbooks in limnology treat lake morphometry as if this were essentially a descriptive subject, but some attempts have been made to demonstrate why morphometry is of fundamental importance for the understanding of lake ecosystem functioning (see, e.g., Håkanson, 2004).

Lakes may be classified and categorized in many ways using different criteria. From a geological perspective,

lakes may be looked upon as causal objects on the face of the Earth. As all geomorphological features, lakes undergo different stages: creation, young age, maturity, old age, extinction. Lakes are generally created by drastic geological events, such as volcanism, tectonic activity, or glaciation. The relief of the basin is under constant alteration by exogenic forces, such as weathering, erosion, transport, and deposition. For example, all 227,000 lakes in Sweden (objects larger than 1 ha; see Table 1) have been influenced by the enormous form-creating power of the latest (but not last) glaciation. Eventually, all these lakes will be filled up and vanish, and the evident relationship between lake size and number of lakes in each size class will disappear. Hutchinson (1957) discussed all major lake types, their origin, morphometric characteristics, and distribution on Earth. He differentiated between 11 major lake types that were divided into 76 subtypes. The 11 major lake types are summarized in Table 2.

Lake morphometric characteristics are crucial for benthic organisms; zoobenthos, benthic algae, and macrophytes are functional groups of paramount importance in most lakes. The bottom sediments constitute the habitat for the benthic animals. Shallow lake areas may be regarded as a “pantry and a nursery” for the entire lake. It has been demonstrated that shallow areas can have a very high bioproduction capacity (many times higher than the most productive areas on land; see Rosenberg, 1985); all three functional groups of primary producers – phytoplankton, benthic algae, and macrophytes – are present in such areas (but not in open water areas in deep lakes), and where there is a high primary production, there is also a high secondary production of zooplankton, zoobenthos, and fish.

To analyze the relative importance of lake morphometry in relation to other factors that may influence fundamental lake variables, such as properties of the catchment area and climatological factors, it is important to realize that any lake variable will depend on factors causing seasonal variations within lakes and on factors causing variations in mean, median, or characteristic values among lakes. Lake morphometry will generally influence variations among lakes, but also many internal processes (sedimentation, resuspension, etc.). This means

that a given pollution load to a lake, for example, of nutrients and/or toxins, may cause very different effects in lakes of different morphometry. Effect-load-sensitivity analyses are of fundamental importance in lake management.

Echosounding and bathymetric map constructions have been discussed in several textbooks (see Håkanson, 2004) and will not be discussed here. All morphometric data, whether calculated using manual methods or digital approaches, such as Geographical Information Systems (GIS), emanate from a bathymetric map. There is a close relationship between the way in which the survey is carried out (the intensity and accuracy of the survey), the error in the bathymetric map, and the information value of the map. If there are no contour lines in the map, the information on the topographical features of the given lake is zero. The information value increases rapidly with the first number of contour lines, but if the number of contour lines becomes high enough, the gain in information becomes negligible, even if more contour lines are added.

Table 3 gives a classification of lake types based on trophic level (bioproduction level). Ultraoligotrophic (very low-productive) lakes are characterized by mean summer chlorophyll-a concentrations lower than 0.1 µg/l and by fish such as char and trout. Oligotrophic (low-productive) lakes have chlorophyll-a concentrations in the range from 0.1 to 1 µg/l and fish like trout and whitefish. One can note the characteristic level of total phosphorous overlap between the classes (see also OECD, 1982). The fish yield in mesotrophic lakes is about 0.9 g wet weight (ww) per m² per year, and by multiplication with lake area and 365 one can calculate an order-of-magnitude value on the annual fish production using this information. Eutrophic (high-productive) and hypertrophic (very high-productive) lakes have higher primary and secondary production.

Morphometric parameters and their role in lake studies

Starting from the bathymetric map, one can define a set of lake morphometric parameters describing lake size, form, and specific features and exemplify why and how these parameters are important in contexts related to the structure and function of lake ecosystems and in regulating the spread and effects of water pollutants.

Among the morphometric parameters, three main groups can be identified (see Figure 1):

- Size parameters: (1) different parameters in length units, such as maximum length, water depth, shoreline length, maximum depth, and maximum breadth; (2) parameters expressed in area units, such as 2D water surface area and 3D bottom area; and (3) parameters expressed in volume units, such as water volume and surface water volume (epilimnetic volume)
- Form parameters, based on size parameters, such as mean depth and shore development (= shoreline irregularity)

Origin of Lakes and Their Physical Characteristics,
Table 1 The number of lakes in Sweden arranged by size (Håkanson and Peters, 1995)

Area (1 km ² = 100 ha)	Number	Cumulative number
>1,000	3	3
100–1,000	19	22
10–100	362	384
1–10	3,987	4,371
0.1–1	19,374	23,745
0.01–0.1	59,500	83,245
0.001–0.01	144,000	227,000

Origin of Lakes and Their Physical Characteristics, Table 2 Major lake types on Earth according to Hutchinson (1957)

1.	Tectonic lakes, e.g., basins in faults (like Lake Bajkal and Lake Tanganyika)
2.	Volcanic lakes, e.g., maars, caldera lakes, and lakes formed by damming of lava flows
3.	Landslide lakes, e.g., lakes held by rockslides, mudflows, and scree
4.	Glacial lakes: A. lakes in direct contact with ice, e.g., lakes on or in ice and lakes dammed by ice B. Glacial rock basins, e.g., cirque lakes and fjord lakes C. Morainic and outwash lakes, e.g., lakes created by terminal, recessional, or lateral moraines D. Drift basins, e.g., kettle lakes and thermokarst lakes
5.	Solution lakes, e.g., lakes formed in caves by solution
6.	Fluvial lakes: A. Plunge-pool lakes B. Fluvial dams, e.g., strath lakes, lateral lakes, delta lakes, and meres C. Meander lakes, e.g., oxbow lakes and crescentic levee lakes
7.	Aeolian lakes, e.g., basins dammed by wind-blown sand and deflation basins
8.	Shoreline lakes, e.g., tombolo lakes and spit lakes
9.	Organic lakes, e.g., phytogenic dams and coral lakes
10.	Anthropogenic lakes, e.g., dams and excavations made by man
11.	Meteorite lakes, e.g., meteorite craters

Origin of Lakes and Their Physical Characteristics, Table 3 Trophic classification of lakes based on fixed steps (a factor of 10) of mean summer chlorophyll-a concentrations (Chl), typical ranges for total phosphorus concentrations (TP), phytoplankton primary production (PrimP in $\mu\text{g C/l-day}$ and $\text{g ww/m}^2\text{-year}$; a factor of 2 is used to calculate g C to g dw ; 5 to calculate g dw to g ww ; the effective depth of the photic zone is equal to the Secchi depth; and the duration of the growing season is set to 150 days), and dominating species of fish in the given classes. Also note that primary and secondary production in highly eutrophic lakes will be reduced by self-shading of algal cells (From Håkanson and Boulion, 2002)

Trophic level	Chl ($\mu\text{g/l}$)	Range TP ($\mu\text{g/l}$)	PrimP ($\mu\text{g C/l-day}$)	Characteristic PrimP range ($\text{g ww/m}^2\text{-year}$)	Characteristic fish yield ($\text{g ww/m}^2\text{-year}$)	Dominating fish species
Ultraoligotrophic	≤ 0.1	< 3	≤ 4.4	≤ 125	0.08	Char, trout
Oligotrophic	≤ 1	1–10	≤ 32	125–380	0.3	Trout, whitefish
Mesotrophic	≤ 10	5–40	≤ 270	380–1,400	0.9	Whitefish, perch
Eutrophic	≤ 100	20–400	$\leq 2,400$	1,400–6,400	3	Perch, roach
Hypertrophic	$\leq 1,000$	> 100	$> 2,400$	$> 6,400$	7	Roach, bream

**Origin of Lakes and Their Physical Characteristics, Figure 1** The lake type may be expressed by morphometrical parameters describing different elements of size, form, and special features.

- Special parameters, like the dynamic ratio and the effective fetch.

The *maximum depth* ($D_{\max}$ in m) is the greatest known depth in the lake. The maximum depth is important in contexts of lake function, especially in defining the lake form factor (= volume development $V_d = 3 \cdot D_{\text{mv}}/D_{\max}$; see later).

Traditionally, the *mean depth* (D_{mv} in m) is defined by the ratio between the lake volume (V in m^3) and the lake area (A in m^2), or $D_{\text{mv}} = V/A$. The mean depth is a most informative and useful parameter in many contexts in limnology. This is exemplified here from the close relationship between mean depth and commercial fish production (Figure 2).

The *maximum length* ($L_{\max}$ in m) is defined by the line connecting the two most remote points on the shoreline. In regular basins, $L_{\max}$ is generally straight and concurs with the maximum effective length (L_{xel}). In irregular lakes, such as oxbow lakes, $L_{\max}$ is a curved line. It may not cross land, but it may cross islands. This rule means

Origin of Lakes and Their Physical Characteristics,
Figure 2 The relationship between commercial fish production and lake mean depth. (Data from Rawson, 1955 and Ahl, 1975.)

that $L_{\max}$ cannot always be given a definite value. It is primarily to be considered as a descriptive measure and has limited use in contexts on lake function.

The *direction of major axis* is defined by the general compass direction of the maximum length.

Traditionally, the *shoreline length* (L_0 , in m) may be estimated in different ways, for example, by a map measurer. To know the shoreline length is important to determine the shore development (L_d) and to calculate production and/or biomass of benthic algae and macrophytes.

The *mean breadth* (B_{mv} in km) is defined by the ratio between the lake area (A in km^2) and the maximum length ($L_{\max}$ in km), i.e., $B_{mv} = A/L_{\max}$.

Traditionally, *total lake area* (A_{tot} in m^2) is calculated by planimeter using a map in a given scale. If the scale factor (SF) is increased, small caps and bays will disappear on the map. This change will primarily affect determinations of shoreline length and not the area determination, since planimetry implies that negative errors (bays) are leveled out by positive errors (caps), provided that the planimetry is carried out on a map of reasonable scale, which is given by $\text{SF} \leq 5,500 \cdot \sqrt{A_{\text{tot}}}$. So, one can regard the area determination as rather independent of the map scale. The total area (A_{tot}) is an important parameter in many limnological contexts, but the *water surface area* (A in m^2) may be even more important. The water surface (A) is given by the difference in total area (A_{tot}) and the total area of islands, islets, and rocks (A_{ins}).

The lake *volume* is a fundamental variable needed to calculate, for example, lake concentrations of all types of substances ($C = M/V$) and the theoretical water retention time ($T = V/Q_{\text{mv}}$; Q_{mv} is the mean tributary water discharge) regulating the retention time of all substances in lakes.

The *relative depth* (D_{rel}) is defined by the ratio between the maximum depth (D_{max}) and the mean diameter of the lake (using the lake water area, A). Small and deep lakes have high D_{rel} values. The relative depth is often used as a measurement of the stability and stratification of water masses and to predict oxygen conditions in lakes.

Traditionally, the *shore development* (shoreline irregularity, L_d) is a dimensionless measure of the degree of shoreline irregularity and defined by:

$$L_d = \frac{L_0}{2} \cdot \sqrt{(\pi \cdot A_{\text{tot}})} \quad (1)$$

where L_0 is the shoreline length (in km) and A_{tot} is the total lake area (in km^2). The L_d value illustrates the relationship between the actual length of the shoreline and the length of the circumference of a circle with an area equal to the total lake area. A perfectly circular basin has a L_d value of 1. Irregular basins have higher L_d values. L_d values larger than 10 are rare, and one of the probably most irregular basins in the world, Lake Mälaren, Sweden, has an L_d value of 9.95. This lake is basically a big archipelago with many communication basins and bays. The shore development is a useful parameter in contexts of sediment sampling. The larger the lake and the more irregular the bottom and also the shoreline, the greater the variability in sediment characteristics and the greater the number of samples needed to obtain a representative mean value for the lake.

The *volume development* (or the *form factor*, V_d , dimensionless) is defined by the ratio between the water volume and the volume of a cone, with a base equal to the water surface area (A in km^2) and with a height equal to the maximum depth (D_{max} in m):

$$V_d = \frac{(A \cdot D_{\text{mv}} \cdot 0.001)}{(A \cdot D_{\text{max}} \cdot 0.001 \cdot 1/3)} = 3 \cdot \frac{D_{\text{mv}}}{D_{\text{max}}} \quad (2)$$

Where D_{mv} is the mean depth. The volume development describes the form of the lake and is also called the form factor. Table 4 and Figure 3 give the classification system for lake form based on the relative hypsographic curves and information on how V_d reflects lake form. One can note that lakes with very convex form (VCx) have small V_d values, and vice versa. This relationship is very important, for example, for internal processes. Shallow lakes have a large percentage of the bottom above the wave base, which is the water depth separating area where wind-induced waves can influence the sediments and above which there are resuspension events. Below the wave base, there is a continuous sedimentation of fine materials and no resuspension from surface waves.

Origin of Lakes and Their Physical Characteristics, Table 4 Classification system for defining the form of lake hypsographic curves and corresponding probabilities based on standard deviations (SD), class limits, and V_d values (Modified from Håkanson, 2004)

Lake form	Label	Probability (%)	Class limits (SD)	V_d
Very convex	VCx	6.5	f(-3.0) to f(-1.5)	0.05–0.33
Convex	Cx	24.2	f(-1.5) to f(-0.5)	0.33–0.67
Slightly convex	SCx	38.3	f(-0.5) to f(0.5)	0.67–1.00
Linear	L	24.2	f(0.5) to f(1.5)	1.00–1.33
Concave	C	6.5	f(1.5) to f(3.0)	1.33–2.00

Origin of Lakes and Their Physical Characteristics, Figure 3 Schematic illustration of relative hypsographic curves for four lakes with different volume development, $V_d = 0.6, 1.2, 1.8$, and 2.4 . Lakes with small V_d have large shallow areas subject to wind/wave-induced resuspension. Lakes with high V_d have greater volumes and steeper slopes, where slope-induced resuspension may occur.

The *dynamic ratio* (DR) is defined by the ratio between the square-root of the water surface area (in km^2 not in m^2), the $\sqrt{A}$ and the mean depth, D_{mv} (in m; $\text{DR} = \sqrt{A}/D_{mv}$). DR is a standard morphometric parameter in contexts of lake resuspension. For lakes $> 1 \text{ km}^2$, one can estimate the fraction of the lake bed where resuspension (a key component of internal loading in lakes) is likely to appear (see Håkanson and Jansson, 1983) from:

$$\text{ET} = 0.25 \cdot \text{DR} \cdot 41^{(0.061/\text{DR})} \quad (3)$$

Wind/wave-induced areas with dominating erosion and transportation areas for fine material (ET areas) are likely to dominate totally the bottom dynamic conditions in lakes with dynamic ratios higher than 4. Slope processes are known to dominate the bottom dynamic conditions on slopes greater than about 4–5%. Slope-induced ET areas are likely to dominate lakes with DR values lower

than 0.05. One can also expect that in all lakes there is a shallow shoreline zone where wind-induced waves will create ET areas, and it is likely that most lakes have at least 15% ET areas.

Some lakes on earth are extremely large and shallow, and one can assume that Lake Tchad, Africa, with an area of $24,000 \text{ km}^2$, a mean depth of 3.2 m and a dynamic ratio of 44.3, must be one of the most particular cases in this respect. It is exceptional for lakes to have DR values larger than 4 and smaller than 0.05.

The *wave base* (D_{wb} in m) is the depth separating transportation area (with resuspension) from accumulation areas (without resuspension). Functionally, this concept is fundamental in limnology since it distinguishes between surface water (epilimnion) and deep-water areas (hypolimnion), see Figure 4.

The *wave base* is related to the wave equation:

$$g \cdot \frac{H}{w^2} = 0.0026 \cdot \left(g \cdot \frac{L_{ef}}{w^2} \right)^{0.47} \quad (4)$$

where g is the acceleration due to gravity (m/s^2), H is the wave height (in m), w the wind speed (m/s), and L_{ef} the effective fetch (in m; see later).

The depth of the wave base, D_{wb} , may also be derived from the ETA diagram. D_{wb} (in m) is then calculated from lake area (note that the area should be in km^2 and not in m^2 in Eq. 5), which is related to the effective fetch (the free water surface over which the winds influence the wave characteristics) and how winds and waves influences the bottom dynamic conditions:

$$D_{wb} = \frac{(45.7 \cdot \sqrt{A})}{(21.4 + \sqrt{A})} \quad (5)$$

This approach gives one value of the depth of the wave base for any given lake.

The following processes influencing internal loading may be accounted for in an approach to predict the ET areas in lakes (see Håkanson and Jansson, 1983):

1. An energy factor related to the effective fetch and the wave base (see the ETA diagram in Figure 5)
2. A form factor related to the percentage of the lake bed above the wave base (see Figure 5)

Origin of Lakes and Their Physical Characteristics, Figure 4 Illustration of important concepts related to stratification, transport, and mixing in a coastal area in a large lake: surface water (epilimnion), deep water (hypolimnion), and thermocline.

Origin of Lakes and Their Physical Characteristics, Figure 5 The ETA diagram (Erosion-Transportation-Accumulation; for more information, see Håkanson and Jansson, 1983) illustrating the relationship between effective fetch, water depth, and bottom dynamic conditions. The wave base (D_{wb}) can be used as a general criterion to differentiate between surface water and deep water in lakes.

3. A lake slope factor related to the fact that slope-induced transportation (turbidity currents) may appear on bottoms inclining more than 4–5%

The *effective fetch* (L_{ef} in km) is often defined according to a method introduced by the Beach Erosion Board (1972). The effective fetch gives a more representative measure of how winds govern waves (wave length, wave height, etc.) than the effective length (L_{el}), since several wind directions are taken into account. The maximum effective fetch attains the highest values close to the shoreline and the minimum values in the central part of a basin. This relationship is important, for example, in

contexts of shore erosion and morphology, for bottom dynamic conditions (erosion-transportation-accumulation) and, hence, also for internal processes, mass-balance calculations, sediment sampling, and sediment pollution. It should be stressed that the theoretical wave base describes average conditions. During storm events, the wave base will be deeper and during calm periods at shallower depths. The wave base also varies spatially within the studied lake.

The hypsographic curve (see Figure 1.4) is obtained by putting depth as well as the cumulative area in percentage on the two axes. The relative hypsographic curve illustrates lake form and nothing but lake form.

The slope (Si) for an arbitrary site in a lake may be determined directly from the echogram, provided that the track follows the same direction as the major slope axis, which can be identified from the bathymetric map. The slope may be given in degrees or as a percentage of the height versus the length. The slope is an important morphometric parameter in contexts of lake sedimentology.

The insulosity (Ins in%), the percentage of the total lake area (A_{tot}) that is occupied by islands, islets, and rocks (Aist; see below for definitions), is estimated by dividing the area of all islands by the total area.

$$\text{Ins} = 100 \cdot \frac{A_{\text{ins}}}{A_{\text{tot}}} \quad (6)$$

The following classification may be used to distinguish islands, islets, and rocks (see Håkanson, 2004):

Area (km ²)	Name
<0.001	Rocks
0.01–0.01	Islets
0.01–1	Islands
>1	Large islands

Summary/conclusions

The way a lake looks and its morphometry (size and form elements) regulate the characteristics of a lake and the way a given lake functions. This section discusses an interpretational code which may be used to gain a better understanding of variations among lakes in fundamental lake ecosystem characteristics. The size and form of lakes regulate many general transport processes, such as sedimentation, resuspension, diffusion, mixing, burial, and outflow, which in turn regulate many abiotic state variables, such as concentrations of phosphorus, suspended particulate matter, pH and many water chemical variables, color, and water clarity, which in turn regulate primary production, which regulates secondary production, for

example, of zooplankton and fish. This understanding is the basis for a wider understanding of lake function and structure.

P

PALEOLAKES

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

All lakes are subject to a variety of extrinsic and intrinsic forcing variables that regulate the subsequent history of the lake. This includes age, climate, catchment, bedrock composition, tectonic and volcanic activity, vegetation, aquatic biota, and human activities. Strictly it is the history of change in these variables and the paleolimnological records of very old or ancient lakes that eventually lead us to the age of the lake.

Paleolimnological records found in three distinct types of archive

Water

Lake water itself and its contents have finite residence times, the time required for the average molecule of water to cycle through the system. In lakes with long residence time measured in say hundreds to thousands of years, the water itself may provide important paleolimnological clues to lake history.

Geomorphology

The geomorphology of the lake basin in its shoreline and shape characteristic features can persist for many thousands of years long after the lake has gone. In this respect, a lake basin evolution is a more useful concept than the static one of lake origin. It is therefore an essential element in the design of a paleolimnological study.

Sediments

Sediments provide the most durable feature since they may persist long after the lake itself, or its geomorphology ceased to exist.

Content archives in paleolimnological are the physical sedimentary inputs to the lake's record. These include terrigenous, chemical, and biogenic sediments; cosmogenic and volcanogenic particles; and fossils that originate outside the lake, like pollen, or in the lake, like fish, aerosols, and water-borne pollutants.

Formation and history of lakes

The formation and history of lakes has intrigued earth scientists for over a century; Hutchinson (1957) recognized 11 major categories of lake origins and since then advances have been made in understanding basin evolution using radiometric dating techniques, seismic stratigraphy, and lake drilling. The following lake classification (after Cohen, 2003) incorporates major elements of Hutchinson's scheme:

Basin closure	Temporal duration (years)
1. Glacial	10^4 – 10^5
2. Tectonic	10^5 – 10^7
3. Fluvial	$\leq 10^4$
4. Coastal	$\leq 10^4$
5. Volcanic	10^4 – 10^7
6. Wind	$\leq 10^4$
7. Solution	$\leq 10^4$ – 10^7
8. Landslide	$\leq 10^3$
9. Meteorite	10^5 – 10^7
10. Artificial	$\leq 10^3$

Paleolakes, Table 1 Ancient lakes (selection)

Lake name	Country	Age (million years)
Aral Sea	Kazakhstan, Uzbekistan	2–20
Baikal (Ozero Baykal)	Russian Federation	Greater than 20
Biwa (Biwa-ko)	Japan	2–20
Bosumtwi (Bosomtwe)	Ghana	1–2
Caspian Sea	Azerbaijan, Iran Kazakhstan, Russian Federation, Turkmenistan	2–20
Crater (2)	Canada	1–2
Eyre	Australia	Greater than 20
Hovsgol (Khuvsgul)	Mongolia	2–20
Issyk-Kul (Isyk-Kul)	Kyrgyzstan	Greater than 20
Lanao	Philippines	2–20
Malawi (Nyasa, Niassa)	Malawi, Mozambique Tanzania	2–20
Maracaibo	Venezuela	Greater than 20
Ohrid	Albania, Macedonia	2–20
Pingualuk	Canada	1–2
Prespa	Albania, Greece Macedonia	2–20
Taho	United States	1–20
Tanganyika	Burundi, Congo (Democratic Republic) Tanzania, Zambia	2–20
Titicaca (Lago Titicaca)	Bolivia, Peru	2–20
Vostok	Polar regions	1–20

PALEOLIMNOLOGY

Barbara Wohlfarth
Department of Geological Sciences, Stockholm
University, Stockholm, Sweden

Synonyms

Lakes as archives of earth history; Limnogeology

Definition

Paleolimnology is the study of lakes and lake sediments to reconstruct past climatic and environmental changes.

Introduction

Lakes have formed and vanished throughout Earth's history (see [Classification of Lakes from Origin Processes; Lakes on Earth, Different Types](#)), but their traces in the form of shorelines, sedimentary rocks, and sediments are often still preserved. The study of lake sediments and sedimentary rocks, to reconstruct environmental and climatic changes through time is called paleolimnology or limnogeology. No clear definition exists that would delimit these two terms, although paleolimnology is often used in the context of younger lake sediments (from present to ca. 2 million years ago), while limnogeology is more used to define the study of older lacustrine sediments and sedimentary rocks.

Paleolimnology as a science began with the study of lake development, i.e., with the observation that lakes change over time from oligotrophic (nutrient poor) to eutrophic (nutrient rich) conditions, as the lake fills with sediment, and the sediment–water interface becomes deoxygenated (Engstrom et al., 2000). The recognition of a “cultural” eutrophication later led to intensive studies of lake eutrophication and lake water acidification connected to human impact; and presently, paleolimnology forms an important tool for assessing natural reference conditions and restoration targets for lake ecosystems (Bennion et al., 2010; Bindler et al., 2010). Parallel with this development, lakes and their deposits have emerged as an important continental archive to reconstruct climatic and environmental changes on shorter (last 12,000 years) and longer time scales (last 2 million years). Ancient lakes (see [Paleolakes](#)) moreover are increasingly recognized as important evolutionary archives which allow assessing of the role of abiotic factors as driving forces for generating biodiversity (Rossiter and Kawanabe, 2000). Excellent overviews on paleolimnology and limnogeology are provided by O'Sullivan (2004); Cohen (2003); Last and Smol (2001a, b, c); Last et al. (2001); Gierlowski and Kelts (2000).

The study of lake sediments

Lake sediments are composed of autochthonous (formed in the lake itself) and/or allochthonous (transported into the lake by water and wind) material which are continuously deposited on the lake bottom (see [Lake Sediments; Sedimentation Processes in Lakes](#)) (Figure 1) (Bloesch, 2004). Anoxic bottom waters and absence of borrowing organisms in certain lakes allow the preservation of seasonal and annual layers (laminated or varved sediments), but in most lakes, sediments have become mixed and their original laminations have disappeared. Changes in the catchment and in the lake itself due to changes in environmental and/or climatic conditions and/or human impact are continuously registered in the sediments. Lake sediments are therefore sensitive recorders of local, regional, and even global changes which can be reconstructed using a variety of physical, chemical, and biological methods, so-called proxies (see [Lakes as Archives of Earth History](#)) (Last and Smol, 2001a, b, c; Last et al., 2001).

Paleolimnology, Figure 1 External and internal environmental factors influencing suspended sediments, sedimentation and sediment formation in a lake basin. 1 = sources of suspended particulate matter (SPM); 2 = transportation and transformation of SPM; 3 = removal of SPM. (From Bloesch, 2004, Figure 8.1.)

Methods used in paleolimnology include bathymetric and seismic surveys to determine lake depth and morphology, sediment thickness, distribution and unconformities, and past lake-level changes. Limnological data are collected to assess the present lake status, catchment land use and, nutrient supply, and to provide calibration data sets for down-core multi-proxy analyses. Sediment cores are obtained using a variety of different coring devices, ranging from gravity and freeze corers for the topmost and least consolidated sediments, to modified Russian corers (for shallow lakes) and piston corers (for deep lakes) to obtain undisturbed sediment sequences. Physical analyses of the sediments include lithostratigraphic descriptions to characterize the sediment type, structure and layer thickness, and mineralogy and mineral magnetic properties to assess the composition of the inorganic sediment fraction; these in turn provide information on, for example, sediment sources, transport mechanisms, depositional environments, and catchment erosion. Chemical sediment analyses comprise inorganic geochemistry which can give information regarding catchment erosion and lake status changes; organic geochemistry to assess, for example, lake productivity, aquatic/terrestrial inputs,

oxygen concentration, source of terrestrial material, biomarkers, and industrial pollution; and stable isotope chemistry to reconstruct changes in lake productivity, lake nutrient status, lipid biomarker sources, sources of lake waters, precipitation, lake hydrology, and lake water temperature. Biological analyses include, for example, pollen, spores, and plant phytoliths to reconstruct catchment, lake and/or regional vegetation history, and human impact; plant macrofossils to assess lake basin vegetation history; charcoal analysis to reconstruct catchment fire history; coleoptera to reconstruct ecosystem changes and temperatures; and limnic and terrestrial microfossils (diatoms, crysophyte cysts, ostracodes, cladocera, chironomids) to reconstruct changes in lake status (pH, salinity, nutrients, trophic state, temperature, precipitation). Chronological analyses (see *Age Determination of Lake Deposits*) provide an age frame for these reconstructions and enable correlations to other geological archives. Modern data sets (e.g., diatoms, chironomids, plant macrofossils, coleopteran, stable isotopes) and associated transfer functions are used to provide quantitative estimates of lake status changes, temperature, and precipitation.

PEIPSI LAKE IN ESTONIA/RUSSIA

Küllil Kangur¹, Andu Kangur¹, Anto Raukas²

¹Centre for Limnology, Estonian University of Life Sciences, Tartu, Estonia

²Institute of Ecology, Tallinn University, Tallinn, Estonia

Introduction

Lake Peipsi is located south of the Gulf of Finland on the border between the Republic of Estonia and Russian Federation, being the largest international lake in Europe.

By its surface area (3,555 km²), Lake Peipsi is the fourth largest lake in Europe after Ladoga, Onego, and Vänern. Peipsi is a very old geographical name of Finno-Ugric origin in the northern part of the Eastern European Plain, but its etymology is uncertain (Jaani, 2001a). In old maps, the lake is depicted since the sixteenth century (Varep, 1995). At different times, the lake is known in slightly different forms: Peibes, Peibas, Peybass, Beibessee, Beibs, and Peips. Ancient name Peipus has persisted mainly in Germanic language literature. In recent literature and geographical maps, the lake appears under two names: Peipsi and Chudskoe (or Chudsko-Pskovskoe) of Russian origin. Slavic people called Finno-Ugric people living to west from Lake Peipsi “tšuds” (from “tšuzoi” meaning “foreign” in Russian).

Location

Lake Peipsi (Figure 1) is situated in the East European Plain between 57°51′–59°01′ N and 26°57′–28°10′ E at 30 m above the sea level. The surface area of Lake Peipsi is 3,555 km² (at the mean water level of 30 m a. s. l.), of which 1,570 km² (44%) belongs to Estonia and 1,985 km² (56%) to Russia (Jaani, 2001a). The lake is shallow with a mean depth of 7.1 m, a maximum depth of 15.3 m, and a volume of 25 km³. These characteristics depend greatly on the overall natural water level fluctuations of 3.04 m over the last 80 years, with an average annual range of 1.15 m (Jaani, 2001b). During the highest water level on May 12, 1924 (31.76 m a.s.l.), the surface area was estimated at 4,330 km² and the volume of water at 32.128 km³. At the lowest water level on November 7, 1994 (28.72 m a.s.l.), these values were 3,480 km² and 20.98 km³, respectively. Thus, the surface area of the lake may vary by 850 km² and the water volume by 11.15 km³.

Lake Peipsi, elongated in the north–south direction, is rather a lake system, consisting of three limnologically different parts (Figure 1). The northern part, Lake Peipsi s.s. (sensu stricto, Chudskoe in Russian), is the largest (2,611 km²) and deepest (average depth 8.3 m). The southernmost part, Lake Pihkva (Pskovskoe), measures 708 km² and is 3.8 m deep on average. The strait between them is Lake Lämmijärv (Teploe) (236 km²; mean depth 2.5 m). The names Lämmijärv and Teploe (“lämmi” in Estonian and “teploe” in Russian means “warm”) are hydrologically motivated because in spring and winter, its water is much warmer than in Lake Peipsi s.s. and Lake Pihkva.

The first inhabitants of the area were Stone Age hunters and fishermen. At the end of the third millennium B.C., cattle breeding and agriculture started to develop. Permanent agricultural settlements were founded in the first millennium A.D., at the end of which period, the Slavs reached the eastern coast of the lake. From the fifteenth to sixteenth centuries, fishing villages appeared on its coasts. At present, the sparsely distributed population (8–9 inhabitants per square kilometers) is mainly engaged in fishery and agriculture. Only 19% live in towns, and the number of habitants is decreasing.

Peipsi Lake in Estonia/Russia, Figure 1 Location of Lake Peipsi.

Islands and coastline

Lake Peipsi has 35 islands and islets with total area of 29 km², which forms 0.8% of the surface area of the lake. The islands are concentrated in the southern part of the lake. The biggest islands are Kolpino (11.1 km²), Piirissaar (7.5 km²), and Kamenka (4.0 km²). In Lake Pihkva, the Talabskij Archipelago consists of three small but high islands. Those were formed along the margin of the ice tongue which penetrated into Lake Pihkva basin during the Otepää Stade of the last glaciation. Island Piirissaar is a natural boundary between Lake Peipsi s.s. and Lake Lämmijärv. The threshold between the two lakes is cut by wide but shallow straits, which are located west and east of the Island Piirissaar and called the Estonian and Russian Gates, respectively. The 520-km coastline of Lake Peipsi is rather straight, without many disjunctures. In the southeastern corner of Lake Peipsi s.s., Raskopel Bay forms a small separate lake.

The catchment

Lake Peipsi belongs to the Baltic Sea watershed and is linked with the Gulf of Finland via the River Narva (Figure 2). The submeridionally elongated catchment area of Lake Peipsi (47,800 km² including lake surface) extends from 59°13' to 56°08' N and from 25°36' to 30°16' E and is shared by Russia (27,917 km²), Estonia (16,323 km²), Latvia (3,560 km²), and, for a negligible part, by Belarus (Jaani, 2001a). The drainage basin is flat, with a highest point of 318 m above sea level. The lake catchment is mainly a gently undulating glaciolacustrine or till-covered plain. Forests and seminatural areas dominate in the lake drainage basin. Agricultural areas cover around 14% of the basin. The total population of the basin provides ca. 1,000,000 inhabitants.

The catchment area of L. Peipsi holds more than 4,500 lakes, the largest of which is a shallow, highly eutrophic Lake Võrtsjärv (270 km²). About 240 rivers and streams flow into Lake Peipsi. Catchment areas of the largest rivers are the following: the Velikaya (25,200 km²), the

Emajõgi (9,745 km²), the Võhandu (1,423 km²), and the Zhelcha (1,220 km²) which account for 80% of the total inflow, thus controlling the water regime of the lake. The Velikaya River drains the largest portion of the Russian and Latvian parts of the basin and discharges into Lake Pihkva. Close to the river mouth is situated the major town of the area Pskov (191,961 inhabitants after World Gazetteer, 2010) which is the main point source of nutrients to Lake Pihkva. The Emajõgi River drains the majority of the Estonian part of the basin and discharges into Lake Peipsi s.s. The major town at the Emajõgi River is Tartu (102,455 inhabitants after World Gazetteer, 2010), which is situated about 50 km from the river mouth. The other bigger rivers include the Piusa (796 km²), the Rannapungerja (601 km²), and the Chernaya (530 km²). The outflowing River Narva (77 km long) is the second largest river after the River Neva flowing into the Gulf of Finland. The annual mean runoff through the River Narva is more than 12.5 km³, which makes about half of Lake Peipsi's water volume (25 km³) and about 3% of fresh water flowing to the Baltic Sea (Haberman et al., 2008). The average water retention time in Lake Peipsi is about 2 years. The water level is not regulated. A strong dependence of the water level on precipitation is characteristic of the hydrological regime of Lake Peipsi. Long-term variability of water level in Lake Peipsi has an expressive cyclic nature (Figure 3).

The geological setting

The thickness of the crust in the Lake Peipsi area increases gradually from about 45 to 50 km toward the south. The sedimentary cover is rather thin, ranging from 300 m in the north to 600 m in the south. Three sedimentary macrounits are recognized: Upper Vendian – Lower Ordovician siliciclastics, Middle Ordovician – Silurian carbonates, and Devonian, mainly siliciclastics (Müdel and Raukas, 1999). Most of Lake Peipsi belongs to the Devonian outcrop area. In the northern part of the lake, dolomitic marls with interlayers of dolostone, siltstone,

Peipsi Lake in Estonia/Russia, Figure 2 Catchment area of Lake Peipsi and the River Narva (after Jaani 2001a).

Peipsi Lake in Estonia/Russia, Figure 3 Mean annual water level in Lake Peipsi in 1920–2010.

and sandstone crop out. In the south, sandstones and siltstones with interbeds of claystones occur with dolomitic marls, dolostones, and limestones.

Peipsi is a natural lake and started about 13,000 radiocarbon (^{14}C) years ago as a big ice-dammed water basin. The Peipsi depression formed as a result of glacial erosion. The gently sloping bedrock surface is about 40 m above the sea level and is at its deepest (15–20 m b.s.l.) in the ancient valleys that were overdeepened by the glacier. The Quaternary cover is relatively thin, mostly less than 10 m. Several stadial till beds of the last glaciation have been found in the depression, differing in color and mineral composition (Raukas, 1978). Older tills have been identified only in the buried valleys. Two well-developed ice marginal belts are recorded by interrupted end moraines via Talabskij Islands in Lake Pihkva and Mehikoorma-Pnevo in Lake Lämmijärv.

Tectonic movements have exerted a strong influence on the formation of the lake. As the northern coast of the lake is lifting more rapidly, there is a gradual southward movement of the lake waters as a result of crustal tilting, which has led to the submergence of several Neolithic settlements in the vicinity of the lake. The chronicle of Pskov records that in 1458, a church was built on the Island of Ozolitsa. The remains of this church are now submerged beneath 0.4–2.5 m of water, and two small islets (Lezhnitsa and Stanok) are all that remains of the former island (Tyumina, 1966). During the last 10,000 years, the uplift in the northern part of the lake basin has been 10 m greater than in the southern portion of the lake (Miidel and Raukas, 1999).

A significant role in the sedimentation and resedimentation of bottom and coastal deposits is played by the lake ice. Almost every spring, ridges of pressure ice, up to 10 m high, are pushed forward against the shore, shaping the coast, redepositing older sediments, transporting huge boulders, and endangering the buildings.

Bottom sediments and shores

Bottom sediments are variegated. In the shallow coastal regions, sediments are relatively coarse-grained

(prevailing sands), whereas in sheltered areas (behind islets and in bays) and in the deep central part of the lake, fine-grained sediments (clayey silts and clays) dominate (Raukas, 1999). Usually, the sedimentary material is carried into the lake by the rivers and as a result of the erosion of the coast and lake bottom; it is then distributed under the influence of waves and streams according to bottom topography. The thickness of deposits is mainly 1–2 m and rarely over 10 m. The mineral and chemical composition of sand, silt, and clay fractions and the content of organic matter (up to 40% in Lake Peipsi s.s., 85% in Lämmijärv, and 35% in Lake Pihkva) as well as microelements is different in various parts of the lake. Fine-grained organic-rich sediments are very cohesive, playing the main role in the circulation of various inorganic and organic pollutants like nutrients and xenobiotics (Punning et al., 2009).

The abrupt cliffed shores (an abrasional escarpments in Devonian sandstone), scarp (an abrasional bluffs in sand, till, or peat), and erosional and flat erosional-accumulation shores are distinguished in Lake Peipsi (Tavast, 1999). The flat erosional-accumulation shores are divided into (1) till shore – an abrasional shore with a protective cover of boulders; (2) gravel shore – an accumulation shore with pebbles and gravelly sediments; (3) sandy shore – an accumulation sandy beach with a ridge of foredunes; (4) silty shore – an accumulation shore with silty-clayey sediments; and (5) artificial shore with manmade structures. During high stand of water, serious damages to the shores are registered. So in the 1920s, the people from Nina village were resettled. In 1987, at the northern coast, the sandy scarp retreated several meters, and near Alajõe, a 4-m-high new bluff formed into dunes. In 2010, serious damages were registered also on the western shore near Ranna.

Climate conditions

Lake Peipsi is situated in the northern region of the temperate zone with variable weather conditions. Summer temperatures can reach high extremes in the Peipsi area. Since 1924, the highest surface water temperature

(28.8°C) was measured in June 27, 1988. Water temperature commonly reaches its maximum in July, but it can happen from the beginning of June to the end of August. The lake belongs to polymictic type of lakes, where the complete mixture of water body takes place several times a year. Due to the lake's large surface area and relative shallowness, waves affect the bottom during the ice-free period. Therefore, thermal stratification is usually episodic and unstable and can be disturbed already by a moderate wind or undulation. Due to mixing, the water of the lake is usually rich in oxygen during the open water period. Lake Peipsi is, as a rule, covered with ice from December till April; however, the start dates of ice-cover and ice-off dates have been highly variable during recent years. Both the formation of ice and the melting process in Lake Peipsi normally take 2–3 weeks, but they can last up to a month. The first ice near the coast is usually formed in early November. In some years, the ice-cover period may last even to the beginning of May. Winter 2007/2008 was the warmest recorded during the whole period of measurements (142 years) in Estonia (Jaagus, 2008). According to measurements by the Estonian Institute of Hydrology and Meteorology, ice-cover destruction started already on January 19, 2008. Furthermore, the ice-cover thickness varies from year to year; the maximum thickness of ice can reach 75 cm and even more in some years. The near-bottom water frequently suffers from oxygen deficiency when the lake is ice-covered.

Lake type and limnetic variability

Lake Peipsi belongs to the shallow unstratified polymictic type of lakes with light water of medium hardness

(average 2.3 m Eq L⁻¹) located on mineral land. The considerable dimensions of the lake and relatively slow water exchange (the ratio of the volume to annual inflow) determine that the retention time for Lake Peipsi is about 2 years. The variability of limnetic parameters, typical for the large lakes, is characteristic for Lake Peipsi. The three lake parts have different morphometry, hydrology, trophic state, and humic content which provide a great variety of biotopes and support organisms with dissimilar ecological requirements. Most of the lake aquatory has lately been mesotrophic, which favors coexistence of the indicators of the meso- and eutrophic state as well as the species preferring a higher trophic state. Total species number of vascular plants and bryophytes is 140, algae are presented by 1,000 species, zooplankton contains about 300 species, macrozoobenthos has more than 400 species, and ichthyofauna includes 37 species.

At present, the lake as a whole is eutrophic, with a clear south-north gradient. The northern and deeper part, Lake Peipsi *s.s.*, is significantly poorer in nutrients than the southern, very shallow part, Lake Pihkva (Table 1).

Using the OECD (1982) classification system, the present-day conditions characterize Lake Peipsi *s.s.* as a eutrophic water body, while the trophic status of Lake Lämmijärv is close to hypertrophic and Lake Pihkva is a hypertrophic basin (Kangur and Möls, 2008). Differences in the water quality between the northern and southern parts of the lake (polarity) is caused, on the one hand, by the differences of natural environmental conditions, but on the other hand, it is determined by local human impact. The catchment area of Lake Pihkva is 2.5 times bigger than that of Lake Peipsi *s.s.* in relation to the surface area

Peipsi Lake in Estonia/Russia, Table 1 Selected morphometric, chemical, and phytoplankton characteristics of Lake Peipsi and its three parts (Lake Peipsi *s.s.*, Lake Lämmijärv, and Lake Pihkva). Water quality parameters are presented as geometric means, and 90% tolerance limits are given in brackets. These estimates correspond to the open water periods (Julian days 100–310 within each year) between 2006 and 2010 (After Kangur et al., 2011 submitted)

^aDIN is the sum of ammonium ion, nitrate ion, and nitrite ion concentrations

and 5 times bigger in relation to the volume of the lake. It means that natural nutrient load to Lake Pihkva is significantly higher than in Lake Peipsi *s.s.* Although Lake Peipsi has been a center of human activities for centuries, the nonuniform anthropogenic impact to the different lake parts has especially intensified during the last decades. The loss of resilience and stability of Lake Peipsi ecosystem poses a risk to biodiversity and ecosystem functioning, as well as to human livelihoods dependent on water ecosystem services.

Multiple stressors

The wide diversity of coexisting human impact (e.g., eutrophication, pollution, overexploitation, introduction of nonindigenous species) and natural (e.g., extreme weather events, fluctuations in water level and temperature, changes in ice conditions and water retention time) stressors are affecting the Lake Peipsi ecosystem dynamics. Multiple stressors are causally linked to socioeconomic and natural processes in the large catchment area of the lake located in different landscapes.

Eutrophication

As in many shallow lakes, eutrophication (nutrient enrichment from human activity) remains the most serious environmental problem for Lake Peipsi triggering changes in the whole ecosystem. Lake Peipsi receives pollution mainly through river water and precipitation directly into the lake. Riverine transport is the most important pathway for input of nutrients from both point and nonpoint sources to Lake Peipsi (Loigu et al., 2008). The majority of phosphorus (P) and nitrogen (N) compounds are carried into the lake by the Velikaya River in the Russian Federation and by Estonian Emajõgi River. These two rivers account for 74% of the total nitrogen load and of total phosphorus load in Lake Peipsi (Loigu et al., 2008). The Velikaya River alone accounted for approximately 52% and 41% of the total phosphorus and nitrogen load, respectively. According to assessments for 2001–2005, Lake Peipsi received 8,324 t N year⁻¹ and 96.5 t P year⁻¹ and 8,532 t N year⁻¹ and 171 t P year⁻¹ from Estonian and Russian parts of the catchment, respectively (Loigu et al., 2008). According to estimates by Buhvestova et al. (2011), the average annual load of nutrients discharged into Lake Peipsi *s.s.* by major Estonian rivers during the period 1992–2007 comprised 5,600 t of N and 179 t of P. However, the major part of the loading from the south reaches Lake Peipsi *s.s.* through Lake Lämmijärv. According to calculations of Rumyantsev et al. (2005), average annual load of P to Lake Peipsi *s.s.* both through the rivers of the Russian part of the catchment and the waterflow from Lake Pihkva during the time span 1992–2003 comprised 280 t. Thus, the value significantly exceeded our calculated average annual Estonian riverine load for the period 1992–2007 (179 t of phosphorus). The average annual area-specific Estonian riverine export of TP to lake Peipsi *s.s.* was estimated at 0.16 kg P ha⁻¹ year⁻¹, while the value of TN was 5.1 kg N ha⁻¹ year⁻¹ (Buhvestova et al.,

2011). However, the estimates of external load to Lake Peipsi from the Russian part of the catchment area have been scarce. Nutrient concentrations in rivers discharging into Lake Peipsi are probably still influenced by nutrient stores from the period of intensive fertilization. The loading of N into Lake Peipsi *s.s.* from the Estonian catchment decreased substantially from the period of intensive agricultural activity in the 1980s to the present time, whereas the loading of P decreased much less. Especially the accumulation of phosphorous in soils will influence P losses on long-term, and the leaching of nutrients can continue for decades after reduced fertilization because of the soil's capacity to retain nutrients.

The increasing difference in total phosphorus (TP) concentrations between the northern and southern parts of the lake (polarity) clearly shows that the input of P from the south is increasing (Kangur and Möls, 2008). This can be considered as an indication of lake eutrophication. In the case of Lake Pihkva, a critical threshold level of P seems to have been exceeded and the lake is “full” of P (Kangur and Möls, 2008). Evidently, Lake Pihkva is losing its resilience. Also, Nõges et al. (2007) supposed the growth of phosphorus loading from the Russian subcatchment in the period 1992–2002, in comparison with loading of 1980s. In contrast, the polarity total nitrogen (TN) concentration in lake water remained relatively stable over the years and can be related to differences in natural conditions between different parts of the lake. Moreover, it refers to the resilience of the lake to year-to-year changes in riverine loads of nutrients. This might be due to in-lake processes: N₂ fixation and denitrification. Moreover, owing to lake's shallowness and relatively long water residence time (about 2 years), the natural processes, especially fluctuations of water level and temperature, can have influenced the lake water quality. As there is a big storage of phosphorus in the sediments of Lake Peipsi (Punning and Kapanen, 2009), lower values of water level in combination with higher summer temperatures could have enhanced the internal nutrient loading, which was followed by increase in TP concentration in lake water. It is especially evident in shallower Lake Pihkva, which is characterized by greater temporal variation of water quality, while the larger, deeper northern part, Lake Peipsi *s.s.*, is more resilient to natural environmental changes. Thus, in-lake TP concentrations can be more sensitive to natural changes in water level and temperature than to year-to-year changes in riverine nutrient loads.

A considerable effort has been invested to reduce external nutrient loads, primarily of P loading to Lake Peipsi. Since 1998, wastewaters of Tartu have been purified chemically, and the efficiency of P removal has been about 85–90%. Wastewaters from Pskov are purified only biologically, and most of phosphorus is not removed yet (Loigu et al., 2008). As Peipsi is situated on the border of the EU, state and regional, economical, and political interests are affecting the water management planning. The transboundary conditions complicate the

implementation of policies that might prevent or mitigate environmental damage in the Peipsi region.

The limnological time series data (from the 1950s to 2010) indicate deterioration of lake water quality and adverse changes in the whole ecosystem of Lake Peipsi. A deterioration of the lake's ecological status is indicated by massive blooms of cyanobacteria, oxygen deficiency, and cyanotoxins in water, shifts in species composition and dynamics of phytoplankton, expansion of reeds and loss of small-sized amphibious plant communities, mass development of epiphyton, accumulation of organic sediments, drastic decrease of zooplankton abundance, changes in the structure of fish community, silting of spawning areas of fish, and summer fish kills. Eutrophication has been the most rapid in the southern parts of the lake: in Lake Pihkva, which is directly affected by pollution coming from Velikaya River in Russia. Doubled TP, dissolved inorganic phosphorus (PO₄-P), silica (Si) and chlorophyll-*a* (Chl *a*) contents, increased total alkalinity (HCO₃⁻) and pH, as well as decline in water transparency and oxygenation conditions during the last decades, indicate an increase in the trophic level of Lake Pihkva (Kangur et al., 2007b).

Macrophytes

Among the rich flora containing about 150 macrophyte species, dominating have always been *Potamogeton perfoliatus* L. among the submergents and *Phragmites australis* (Cav.) Trin. ex Steud. among the emergents (Mäemets et al., 2010). Some species of mesotrophic stage became extinct in the 1980s (*Isoetes echinospora* Durieu and *Subularia aquatica* L.) or are suppressed (*Alisma gramineum* Lej., *Potamogeton filiformis* Pers., etc.) (Mäemets and Freiberg, 2004). In Lake Peipsi, the expansion of reeds has been the most evident result of eutrophication during the last 40 years. Increase of reeds is especially remarkable in Lake Peipsi s.s. where mesotrophic status is replaced by eutrophic. Since the end of the 1960s, the average biomass of reed per square meter has increased more than 70 times in the northern part of the lake (Mäemets, 2005). The success of reeds on Lake Peipsi has three main causes: (1) high nutrient loading, especially in the 1970s and 1980s, (2) low-water period at the end of the 1960s and beginning of the 1970s, and (3) diminishing or cessation of grazing (Mäemets and Freiberg, 2004). Expansion of reeds causes decrease of floristical diversity and increase of uniformity of lake parts. The expanding reed belt provides favorable growth conditions for the wind-sensitive shade-tolerant species of hypertrophic waters (*Spirodela polyrrhiza* Schleid., *Ceratophyllum demersum* L.) (Mäemets, 2005). Tall reed shoots shadow the habitats of the light-demanding small-sized species, and slowly decomposing litter covers large areas. Recent depth limit of reeds reaches mostly 1 m. Their expansion seems to be quite analogous to the result of fertilization experiments on grasslands where addition of nutrients favored the decrease in species number and prevalence of large-sized graminaceous species (cit.

Mäemets et al., 2010). Eutrophication has expanded northward along the longitudinal axis of the lake. So the reeds have occupied the northwestern shore of the lake during the 1980s and have appeared on the northern dyne shore during the last decade. Their establishment there is hindered by bottom conditions (moving sand) and changing water level. However, on the more flatten and sheltered shore stretches permanent stands exist now also in the northern shore. The growth rate of reed stands in eutrophic conditions may exceed 1 m per year.

In parallel with the direction of the eutrophication northward, expansion of nutrient-demanding species toward the northern part has taken place already in 1970s, when there appeared *Zannichellia palustris* L., *Elodea canadensis* Michx., *Ranunculus circinatus* Sibth., *Ceratophyllum demersum* L., *Lemna trisulca* L., *Spirodela polyrrhiza* (L.) Schleid., and *Potamogeton pusillus* L.

The richest flora of Lake Peipsi was characteristic for the period of the coexistence of nutrient-demanding and nutrient-sensitive species in 1970–1980. Macrophyte species richness has decreased in parallel with lake eutrophication. Comparing the frequency of the 67 species in the stations around the whole lake in 1970–1980 and in 1997–2007, a statistically significant decline occurred in the case of 20 taxa, among them frequency decreased twofold for 15 species. The most obvious reason for these changes is the occupation of the littoral by reeds (Mäemets et al., 2010).

Phytoplankton

Lake Peipsi is inhabited in all ecotopes (pelagial, littoral, periphyton, benthos) by more than 1,000 algal taxa identified up to now: cyanobacteria (*Cyanophyta*) – 186; diatoms (*Bacillariophyta*) – 539; green algae (*Chlorophyta*) – 331 species; and other groups – 138 species. Phytoplankton of open water area consists of about 500 algal species. The species composition in Lake Peipsi is characteristic for large lowland lakes like Ladoga, Onego, Vänern, Vättern, and Mälaren and resembles also that of Ancylus Lake (Davydova, 1981). Diatoms prevailed in the plankton taxonomic composition and biomass during most of the year; however, cyanobacteria exceeded them in summer and autumn seasons in the last decades. A drop in diatoms occurred in Lake Peipsi s.s. from 2000. The abundance of former dominant species in cold seasons, mesotrophic *Aulacoseira islandica* (O. Müller) Simonsen, is decreased at present. At times, eutrophic *Aulacoseira granulata* (Ehr.) Sim. and *A. ambigua* (O. Müller) Sim. occupy an important part in plankton. The unicellular centric species (genera *Cyclotella*, *Stephanodiscus*, *Cyclostephanos*) are also important. Among cyanobacteria, the genera *Microcystis*, *Anabaena*, *Aphanizomenon*, and *Gloeotrichia echinulata* (J.S. Smith) P. Richter cause massive water blooms in favorable weather conditions, particularly in nearshore areas as well as in the southern hypertrophic lake parts. Nuisance cyanobacterial blooms

are not a phenomenon of the modern industrial society. Massive development of cyanobacteria was noticed in Lake Peipsi sometimes since 1895 (review Laugaste et al., 2001). The share of cyanobacteria in phytoplankton biomass increased during the last decades from 20% to 60% in Lake Peipsi s.s., and from 30% to 90% in the southern parts of the lake in summer months (Haberman et al., 2010). In recent years, strong and long-lasting (up to November) algal blooms were repeatedly observed in the lake. Depending on weather conditions, the duration of algal blooms has increased. Along with continuous hot weather and decreasing water level, the abundance of algae increased in July–August 2002 and the Chl *a* content in the nearshore water reached 400 mg m^{-3} and the phytoplankton biomass 250 g m^{-3} in July–August (Kangur et al., 2005). The ecological situation in the lake worsened quickly and led to a strong fish kill. High concentrations of cyanotoxins were determined repeatedly in Lake Peipsi water during cyanobacterial blooms. Microcystins were identified in bloom samples, when *Anabaena* spp. and *Microcystis* spp. dominated in Lake Peipsi (Tanner et al., 2005). Maximum concentrations of microcystins in water were determined on September 8, 2002 ($586 \text{ } \mu\text{g L}^{-1}$), and on July 5, 2005 ($65 \text{ } \mu\text{g L}^{-1}$). No microcystins were found in the samples from massive bloom of mainly *G. echinulata* in summer 2002.

Zooplankton

In zooplankton species composition and abundance, important changes have occurred during the last century. The species of oligotrophic waters *Holopedium gibberum* Zaddach lived in Lake Peipsi from 1909 to 1964, but it has not been encountered there later. Until the 1930s, no juvenile *Dreissena polymorpha* (Pallas) were found in the zooplankton of Lake Peipsi because adult *D. polymorpha* did not yet inhabit this water body. The cladoceran species *Daphnia galeata* Sars is found in the lake since 1950 (Haberman, 2001).

At present, with respect to number, small rotifers (*Rotatoria*) dominate in Lake Peipsi zooplankton throughout the year, while with respect to biomass, considerably larger cladocerans (*Cladocera*) and copepods (*Copepoda*) prevail, especially *Eudiaptomus gracilis* (Sars) and species of genera *Daphnia* and *Bosmina*. In spring (May), rotifers and copepod juveniles prevailed; in summer and autumn, the species of the genera *Daphnia*, *Bosmina*, and *Eudiaptomus gracilis* (Sars) were commonly dominating, but their biomass was different. In early summer (June) and in late summer (September), the role of the genus *Bosmina* and copepods in the zooplankton biomass was greater than in July when cladocerans, particularly *Daphnia cucullata* Sars, were prevalent. Zooplankton biomass in summer (mean values for July–August, 1997–2006) was 2.23 mg L^{-1} and abundance was 510 ind. L^{-1} .

In parallel with increasing cyanobacterial blooms, an essential decline occurred in zooplankton. A significant decrease in the biomass of all zooplankton groups – cladocerans, copepods, and rotifers – occurred from

2001 (Haberman et al., 2010). The most essential decline affected rotifers. The abundance of *D. polymorpha* veligers also decreased significantly in the whole lake. The decrease in the amount of zooplankton reflects deterioration of lake water quality. The effect of planktivorous fishes on the zooplankton was significant in the 1960s when the fish community was dominated by planktivorous vendace and smelt. However, the recent decrease in zooplankton cannot be explained by the increased pressure of fishes due to vanished populations of planktivorous fish (Kangur et al., 2008a). However, cyanobacterial blooms and presence of cyanotoxins are probably the main reasons for the significant decrease in the amount of zooplankton, particularly rotifers (Haberman et al., 2010).

Zoobenthos

The three main groups of macrozoobenthos in Lake Peipsi are *Chironomidae* (with 111 taxa), *Mollusca* (83), and *Oligochaeta* (59) which form more than half of the species number (Kangur et al., 2008b). The abundance and biomass of macrozoobenthos (average without large mollusks $2521 \pm 96 \text{ ind. m}^{-2}$ and $12.3 \pm 0.5 \text{ g m}^{-2}$ in 1964–2006) as well as species diversity are continuously high in Lake Peipsi. Excluding large clams, chironomids and oligochaetes are dominating in the bottom fauna. The typical community of eutrophic lakes dominated by *Chironomus plumosus* (L.) (*Chironomidae*) and *Potamothenis hammoniensis* (Mich.) (*Tubificidae*) has inhabited the profundal of Lake Peipsi presumably during hundreds of years. Small bivalves of the families Pisidiidae and Sphaeriidae are still abundant in the profundal. Several oxyphilous species characteristic of mesotrophic or oligotrophic lakes, as chironomid larvae of *Monodiamesa bathyphila* (Kieffer) and oligochaetes *Lamprodrilus isoporus* Mich., *Tasserkidrilus acapillatus* (Finog.), *Peipsidrilus pusillus* Timm, and *Limnodrilus profundicola* (Verrill), are present in Lake Peipsi. However, the introduction/invasion of alien species has irreversibly changed the benthic invertebrate community of Lake Peipsi. The zebra mussel *D. polymorpha* that invaded Lake Peipsi in the 1930s (Mikelsaar and Voore, 1936) forms now the most significant animal population of the lake in terms of biomass. The biomass of zebra mussel exceeds the biomass of all other bottom animals about 20 times. The impact of zebra mussel on water quality in Lake Peipsi, through the filtration of phytoplankton and increasing the sedimentation rate of suspended matter, is significant. However, zebra mussels and also zooplankton cannot feed on large colonies of cyanobacteria. The Baikalian amphipod *Gmelinoides fasciatus* (Stebbing), a successful invader in Europe, was introduced into Lake Peipsi with the intention to improve the feeding base of fish in the 1970s. The newcomer was at first explosively distributed near the site of introduction in the eastern shore of the lake and followed by the distribution in the western shore in the 1980s (Timm and Timm, 1993). Until the 1970s, only two gammaridean species occurred in Lake

Peipsi: *Gammarus lacustris* Sars, among macrovegetation and stones in the littoral, and *Pallasiola quadrispinosa* Sars, in open sand bottom habitats. Intentional introduction of *G. fasciatus* from Siberia has irreversibly altered littoral benthic communities in Lake Peipsi. At present, *G. fasciatus* is the most abundant macroinvertebrate species in the nearshore area, while the native gammarids *G. lacustris* and *P. quadrispinosa* appear to be extinct and oligochaetes have declined (Kangur et al., 2010). The distribution pattern of the invader close to water edge in summer makes it mostly inaccessible for adult fish. Being highly mobile, *G. fasciatus* is not sensitive to water level fluctuations in shallow lakes. These characteristics increase its success.

Fish community characteristics

Lake Peipsi is inhabited by 37 fish species (Kangur et al., 2008a). Over the past 80 years, no species have been lost from Lake Peipsi; on the other hand, there is neither any information about invasion of new species into the fish community. Lake Peipsi has been rich in fish production, where smelt, *Osmerus eperlanus eperlanus* m. *spirinchus* Pallas; vendace, *Coregonus albula* (L.); and pikeperch, *Sander lucioperca* (L.) have been the main commercial fishes in the lake at different times. However, despite the same species composition and interannual variations, the commercial fish catch was seen to decline to about half of the catches taken 80 years ago. According to commercial statistics, the average annual catch of fishes was 11,650 t (33 kg ha⁻¹) in 1931–1940 and 5,593 t (e.g., 16 kg ha⁻¹) in 2005–2009. In addition, substantial alterations in relative species dominance have been noted. In the 1930s, the main commercial fish were smelt (43% of total catch); roach, *Rutilus rutilus* (L.) (16%); perch, *Perca fluviatilis* L. (7%); and bream, *Abramis brama* (L.) (7%). In 2005–2009, most of the commercial catches comprised pikeperch (34%), bream (17%), roach (14%), and perch (13%). Less abundant commercial fish species were pike, *Esox lucius* L.; burbot, *Lota lota* (L.); and ruffe, *Gymnocephalus cernuus* (L.). Peipsi whitefish, *Coregonus lavaretus maraenoides* Poljakow; vendace; eel, *Anguilla anguilla* (L.); rudd, *Scardinius erythrophthalmus* (L.); ide, *Leuciscus idus* (L.); tench, *Tinca tinca* (L.); and white bream, *Blicca bjoerkna* (L.) have been occasionally represented in catches. The Red Book of Estonia (2011) includes wels, *Silurus glanis* L.; grayling, *Thymallus thymallus* (L.); bullhead, *Gottus gobio* L.; asp *Aspius aspius* (L.); mud loach, *Misgurnus fossilis* (L.); vendace; and Peipsi whitefish.

Fish stocks of Lake Peipsi are mainly affected by (1) overexploitation, by (2) ecosystem changes (e.g., eutrophication, degradation in water quality, siltation of spawning grounds, shifts in food webs), and also by (3) natural processes (e.g., heat waves, increases in water temperature, changes in ice conditions, fluctuations in water level). Concurrent worsening ecological conditions in Lake Peipsi and high fishery pressure (including pouching, unregistered caught quantities, excessive

number of professional fishermen) is threatening fish stocks, causing a substantial decrease in catches and triggering changes in community structure. The effect of fishing is the most important human impact on the fish community in Lake Peipsi. Even though the fishery methods have changed, the fish stocks of the lake have repeatedly suffered from the overfishing (Kangur et al., 2007a). Investigations made by von Baer (1852) in the middle of the nineteenth century targeted the reasons for the declining stocks and catches of main commercial fish species (mainly bream) in Lake Peipsi and concluded that the main reason was the intensive use of fine-meshed towed fishing gear as well as the blocking of the spawning migration routes of bream by large traps. In the 1950s, fishing was markedly intensified in Lake Peipsi due to high demand for food after WW II. Therefore, trawling was reintroduced in the lake and expanded drastically. Extensive use of fine-meshed towed fishing gear (e.g., trawls replaced later by bottom seines) affected mostly recruitment of pelagic predator, pikeperch, killing young specimens of this fish in large quantities. The next drastic increase in fishing pressure was caused by the sociopolitical changes brought along with the collapse of Soviet Union. At the beginning of 1990s, fishing became a highly significant source of employment. Therefore, the number of fisherman doubled in comparison with the end of Soviet period. During the last decade, the fishery in the lake is regulated according to the Estonian–Russian Fisheries Agreement from 1994, whereas since 2000, quotas are established for all commercial species.

Fishery has direct negative impact on the total stock and on the size composition of the fish community. Particularly, pikeperch population is affected because larger specimens are almost completely removed leaving an unbalanced population of only a few young year-classes. Substantial decrease in the abundance of larger specimens of pikeperch in L. Peipsi means that the predatory pressure of its stock has changed and directed to smaller prey. Human-induced imbalance within fish stocks (e.g., change of predator versus prey proportions) has cascading effect through food webs. The ecological role of top predators as the main regulators of the abundance of coarse fish has diminished.

Although the population dynamics of several fish species, especially of big predators, is to a large extent controlled by fishery, the long-term effects of concurrent eutrophication and environmental extremes (e.g., heat waves, water level fluctuations, changes in ice conditions) on the fish community are considerable. Since the 1930s, several marked changes occurred in the composition of fish community. By the turn of the decade 1980/1990, a sharp decline in vendace population coincided with a major increase of pikeperch. The abundance changes in the Lake Peipsi fish community have gone in opposite directions for cold-adapted as compared with warm-adapted species (Kangur et al., 2011 submitted). The fish community has shifted on a long-term scale from clean- and cold-water species like smelt, vendace, whitefish,

and burbot toward more pikeperch and bream, which prefer productive warmer and more turbid waters. Lake Peipsi is no longer a suitable habitat for smelt, vendace, whitefish, and burbot, which prefer colder oligotrophic water and that richer in oxygen. However, the new conditions are suitable for pikeperch and bream, which are generally classified as warm-water-tolerant species favored by eutrophic conditions. Although the fish species list has not changed in Lake Peipsi during the last decades, there have been significant shifts in relative dominance and in the prevalent feeding habits of the fish species. A major decrease in pelagic planktivores (e.g., smelt, vendace, Peipsi whitefish) can be considered as the main indicator of such significant shifts.

Besides small, systematic trends that have become important in the longer term, major abrupt changes have occurred repeatedly during the last half century in the Lake Peipsi fish community. Concurrent eutrophication and sudden environmental extremes (e.g., heat waves) can cause long-lasting and irreversible changes in the fish community of the lake. In Lake Peipsi, the effects of eutrophication have seemed to increase dramatically in hot and dry summers, when water level decreases sharply, and all the usual water quality parameters (e.g., water transparency, nutrient content) have demonstrated the worsening of the lake's ecological health (Kangur et al., 2005). Thus, the lake's status can shift abruptly, e.g., in response to drought, causing unexpected catastrophes in its biota (e.g., fish kills). Current data indicate that recent climate warming in summer time (together with severe heat waves) and nutrient enrichment in the Lake Peipsi ecosystem are acting in the same direction: both are increasing the probability of fish kills, which have become more frequent and extensive. In the summers when cyanobacterial (blue-green algae) blooms, hot and calm weather, and consistently high water temperature (up till 26–28°C) co-occur, fish kills have been repeatedly observed in Lake Peipsi over the past five decades. Although mass growth of cyanobacteria has been documented in the lake since the nineteenth century (Laugaste et al., 2001), eutrophication (the addition of the nutrients to the lake) appears to have raised the intensity of the blooms. A fish kill during a bloom of *Aphanizomenon* sp. was first described in 1959, when a sudden large-scale smelt mortality occurred in the southern part of the lake, Lake Pihkva (Semenova, 1960). The next massive smelt kill in summer 1972, during a calm warm period and strong cyanobacterial bloom, affected the entire lake. In the following years (1973–1974), no smelt were caught; however, a quick recovery of stock occurred in the following 2–3 years. In a similar fashion, subsequent hot summers with cyanobacterial blooms had long-term negative effects on the smelt population. In recent years, the abundance of smelt population has reached a historically minimum level. After extreme weather events and fish kill in 1988, the vendace population collapsed and has not yet returned to its previous levels. Recently, however, besides cold-water fish (smelt, vendace), other fish species, especially

bottom-dwelling fish such as ruffe and juvenile fish of several species, were also seriously affected by concurrent effects (Kangur et al., 2011 submitted). During the fish kills in 2002 and 2010, ruffe has been seriously affected. This may be due to the fact that the heat waves and cyanobacterial blooms can lead to the bottom layers of the lake water becoming oxygen-deficient. As environmental extremes have become more frequent and summer fish kills have involved larger area, there was serious damage to the fish populations which eventually may lead to the extinction of some fish species (Kangur et al., 2011 submitted). This has already been proven to be correct for smelt, a previous key species in the fish community.

Socioeconomic significance

Lake Peipsi is of great economic significance, first of all as the drinking water source for the Estonian industrial town Narva and its sister town Ivangorod on the Russian side of the border, but also in terms of water transport, fishery, and energy production. Its bottom deposits hold great reserves of curative mud and building materials, and its waters cool the huge kettles of the Baltic and Estonian Thermal Power Plants and drive the turbines of the Narva Hydropower Station. The beaches of the lake, especially in the northern and eastern parts, have a big recreational value. Fishing is an important sector of rural employment in the Peipsi region and an essential part of the lifestyle in the lake's coastal villages. Fish stocks of the lake have been remarkably high, which makes it economically important for both commercial and recreational fishermen.

History of research

Hydrobiological studies on Lake Peipsi have a long tradition; fishery investigations began already with the work of Karl-Ernst von Baer in 1851–1852. Since 1950, systematic hydrochemical studies are carried out on the lake. Annual hydrobiological monitoring of Lake Peipsi has been carried out by the Institute of Zoology and Botany since 1962 and monitoring of coasts by the Institute of Geology since 1981. Today, this work is part of the Estonian State Environmental Monitoring Programme, which gained legal ground in 1993. The results of the monitoring constitute the main scientific base for political decisions to be passed by the state and local authorities. Unfortunately, most studies since 1992 have been on the Estonian part of the lake. However, regular joint Estonian–Russian expeditions to the whole lake have been arranged since 2001. Several monographs about Lake Peipsi have been published during the last decade (Miidel and Raukas (1999); Nõges (2001); Pihu and Haberman (2001); Haberman et al. (2008)).

PHOSPHOR EXCHANGE SEDIMENT-WATER

Kurt Pettersson
 Department of Ecology and Genetics, EBC, Uppsala University, Norrtälje, Sweden

Introduction

Lake sediments play a crucial role in the phosphorus metabolism in lakes. The impact depends on the capacity to retain and thereby decrease the phosphorus availability in the lake water and secondly, on the ability to release phosphorus when environmental conditions change. The particle composition, prehistory, and binding capacity of the sediment govern its behavior. The general view until the 1970s was that sediments acted as sinks for phosphorus with the exception of periods with anoxia in the bottom waters, when iron-bound phosphate is released to the hypolimnion of stratified lakes (Einsele, 1936; Mortimer, 1941, 1942). During the last decades, more knowledge has been gathered (Boström, 1982; Löfgren, 1987; Rydin, 1999) and a much more complicated picture has developed, emphasizing the important role of internal loading for lake water quality and especially for the summer blooms of cyanobacteria in lakes.

The internal loading from lake sediments will often determine the level of eutrophication of the lake and the time lag for recovery after reduction of the external loading. Internal loading is most important during summer when the water temperature is high, speeding up the lake processes. The pool of phosphorus bound to particles in the surficial sediments (10 cm) is vast (100 fold) in comparison to the phosphorus pools in the water column. Phosphorus can leave the sediment in a dissolved state mainly as phosphate or as particles. In the latter case, there are two major ways: as resuspended sediment particles (detritus) or by migration of resting stages of phytoplankton. Even if a very small share is released, it will have significant impact on the phosphorus concentration in the lake water.

The distribution of phosphorus forms in sediments has been investigated since the 1950s. Generally, vertical profiles of sediment phosphorus concentration, expressed on a dry weight basis, show an increasing concentration toward the sediment surface in eutrophic lakes. This increasing vertical profile continues into the water, when looking at sedimenting particulate matter (sedimentation

traps) and suspended matter. The different phosphorus forms are determined by sequential extraction and labile, aluminum-, iron-, and calcium-bound phosphorus can be separated. The residual is mainly organically bound phosphorus. Organic as well as iron-bound and labile phosphorus are the three fractions increasing in the vertical profile mentioned above. An example of the fractional phosphorus composition from Lake Erken, Sweden illustrating this is shown in Figure 1.

A number of environmental factors are important in the mobilization process. To leave the sediment in a dissolved state, phosphorus must be mobilized by physical, chemical, or biological processes and then transported to the lake water. The splitting mechanisms includes desorption, dissolution of precipitates and complexes, ligand exchange, and enzymatic hydrolysis of organic ester bonds. Most studies indicate that sediment bacteria have a significant role in uptake, storage, and release of phosphorus including anaerobic release of iron-bound phosphorus. The redox potential in the sediments affects reduction of iron (III) to iron (II) and a subsequent release of phosphate. At higher pH levels (i.e., in shallow lakes with high primary production), hydroxide ions replace phosphate causing ligand exchange. A high water temperature increases the bacterial activity giving lower redox potential and a higher production of enzymes. This means that phosphorus can be released from lake sediments although the oxygen concentration in the water is high when the water temperature is high during summer.

Several phytoplankton species have resting stages overwintering in the sediment. When growth is induced, they leave their habitat in order to shift their life form to a pelagic one. In Lake Erken, Sweden, the cyanobacteria *Gloeotrichia echinulata* has been shown to contribute to

Phosphor Exchange Sediment-Water, Figure 1 Phosphorus forms in sediment, settling, and suspended particles in Lake Erken, Sweden.

Phosphor Exchange Sediment-Water, Figure 2 Increase of total phosphorus concentration in Lake Erken and the contribution of migrating *Gloeotrichia echinulata*.

the internal loading of phosphorus during summer. The floating capacity of the colonies makes them able to pass the metalimnion and migrate to the epilimnion, transferring phosphorus from sediments to the upper water strata (Figure 2).

PLAYA LAKE CHAINS: THE EXAMPLE OF THE YENYENING LAKES OF THE UPPER AVON RIVER CATCHMENT OF WESTERN AUSTRALIA

Jenny A. Davis¹, Paul A. Carling²

¹School of Biological Sciences, Monash University, Clayton, VIC, Australia

²School of Geography, University of Southampton, Southampton, UK

Introduction

The term “playa” or “pan” applies to individual arid zone basins of varying size and origin that are subject to ephemeral surface water flows (Shaw and Thomas, 1989) such that lakes may occur within playas as permanent or ephemeral features. Playas in Australia are often geologically young (Quaternary) features developed in arid environments and are often dry due to evaporation (Boggs et al., 2006). Although playas are a response to tectonics, climate change, and eolian and fluvial processes, the majority of the scientific literature considers either their origin within a regional context, or the development dynamics of individual playas (e.g., Bettenay, 1962). However, where playas are developed within paleodrainage channels, they may exist as isolated features, but more often they exhibit a degree of hydrological interconnectivity with other playas to form “playa chains” such that the development history of an individual playa cannot be addressed without consideration of its neighbors.

Dryland salinity is a major environmental issue in inland Australia, particularly in Western Australia and South Australia, and has been estimated to affect over 2.2 million hectares (State Dryland Salinity Committee, 1990). The Wheatbelt region of the southwest of Western Australia has the largest area of land affected by salinity, and this is predicted to increase to 8.8 million hectares by 2050 (Australian Natural Resources Atlas, 2000). Isotopic studies have shown that some salt in the soils are of marine origin and accumulate by winds transporting salt inland from the sea (Chivas et al., 1991). However, in this region the replacement of deep-rooted perennial species with shallow-rooted annual cropping species (Wood, 1924; Mulcahy, 1978; Schofield et al., 1988) has resulted in waterlogging and extensive salinization of rivers, streams, and valley floors. The reduction in evapotranspiration associated with widespread land clearing led to a rise in the level of the saline aquifer and mobilization of salt previously stored deep within the soil profile.

Prior to clearing, Wheatbelt catchments were essentially completely vegetated with a diverse range of woody plant communities whose distribution was controlled by climate and soil type (Beard, 1981). The vegetation was capable of using deeply infiltrated water during the dry season. Most of the annual precipitation was evaporated or transpired. However, there is anecdotal evidence that the drainage systems prior to the twentieth century were fresh or at least less saline than today (Cross, 1833; YLMS, 1996) with well-vegetated riparian zones. With clearing, the water balance changed to one of reduced annual evaporation and interception and increased runoff and recharge (Hatton et al., 2003). Runoff onto and through valley floors is considered to have increased by a factor of 5, and increased groundwater recharge is filling deep sedimentary materials and bringing highly saline water to the surface. Diffuse recharge has also increased on slopes and ridges with additional hydraulic heads forcing groundwater toward the valleys and resulting in increased discharge of water and salt to streams and wetlands. The changes in local climate due to forest removal and the reduction in vegetation cover must also have implications for eolian processes. The Yenyening Lakes and Salt River sections of the Upper Avon catchment (Figure 1) form a series of interconnected playa lakes and seasonally wetted salt pans confined within a paleochannel. The Yenyening Lakes are part of a regional complex of playa lakes (Killigrew and Gilkes, 1974) that only recently have received detailed scientific scrutiny (e.g., Boggs et al., 2006). The Yenyening Lakes are considered to be a very significant feature in the hydrology of the Wheatbelt (WRC, 2002) because all the drainage of the Lockhart and Yilgarn catchments (which cover a significant portion of the region) flows through them into the Avon–Swan system. Significantly, the morphology of the playa chains is a response to the geology and the present climatic, topographic, and hydrographic

controls, but also the morphology has characteristics inherited from prior climatic and hydrological systems that require elucidation.

Climate and hydrology

The regional climate is characterized by hot, dry summers and warm, wet winters (Gentili, 1971, 1993). The average annual rainfall in the region is 350 mm, and the average annual evaporation is approximately 2,100 mm (WRC, 2002). Prevailing winds are strongest from the southwest during summer but from the northeast during winter.

Although the name “Salt River” suggests that river has always been saline, this epithet probably referred to the episodic pulses of salt that would have moved through the river when sufficient rainfall occurred in the uppermost areas of the catchment to move salt water through from playas much further to the east and south, such as Lake Deborah and Lake Grace.

A simple salt and water balance model for the Yenyening Lakes System was developed by Bari (2002) from data available over the period 1973–2000. During that period there was an average annual inflow of 39.5 million cubic meters and outflow occurred in most years. Approximately 92% of the total annual input was lost by flow out to the Avon River and 8% by evaporation processes. Loss through seepage to the deep aquifer was considered to be negligible. The median salinity of the playas was 60,000 mg/L TDS, the annual average salt input was 381,000 t, and 99% of the stored salt was lost due to overflow.

The Yenyening Lakes Management Strategy (WRC, 2002) suggested that the generalized description of groundwater hydrology in the Wheatbelt can be applied to the Yenyening system. Prior to forest clearance, the hydrological system was in balance with the water table maintained at a constant depth and the native vegetation able to use all of the rainfall infiltrating the soil profiles. This situation was dramatically altered through land clearing. The water table has risen and the discharge of saline groundwater to the surface drainage has increased. A substantial area with depth to groundwater from 0.5 to 1 m adjoins the main drainage line, and the playas, channels, and the Salt River are considered to be fully saturated (Smith, 2002). Land Monitor (2000) plots indicated that the area of salinized land in the region had increased between 1989 and 1998 and would continue to increase significantly (Smith, 2002).

Geology and geomorphology

The geology and geomorphology of Western Australia was summarized by White (2000), who noted that satellite imagery reveals that the modern landscape contains a mixture of ancient and modern features. Many modern rivers and playas are in the valleys of ancient paleodrainage lines. The paleodrainage patterns of the state were established by the end of the Cretaceous or early in the Tertiary (65–60 million years ago) (Van de Graaff

Playa Lake Chains: The Example of the Yenying Lakes of the Upper Avon River Catchment of Western Australia,

Figure 1 Location of the study area in southwestern Australia. The *inset box* shows the location of the Avon River tributaries and the Yenying Lakes. The *inset circle* shows the chain of playa lakes located between the south branch of the Avon River and the Salt River.

et al., 1977; Zheng et al., 1998). White (2000) recognized seven major paleodrainage provinces on the Yilgarn Craton. The province in which secondary salinization has been particularly prevalent is that of south-to-north trending valleys that drain into rivers flowing into the Indian Ocean (the Avon–Swan and Canning Rivers).

A comprehensive study of the geomorphology, geology, and paleohydrology of the Salt River system by Salama (1997), within the context of the regional development of the drainage system (Beard, 1999, 2000), noted that the Salt River system connects the saline playas of the Yilgarn catchment in the eastern ancient zone with the rejuvenated Avon–Swan system in the west and has probably occupied the same course since the early Tertiary. At that time, the uplift of the Yilgarn Craton and the formation of the Darling Scarp dammed the river and caused the formation of a large inland lake. This large paleolake at Yenying (named Yilgarn Lake) persisted until the opening of the northern outlet of the Avon which occurred during exceptionally wet periods after denudation reduced the height of uplifted areas (Salama, 1997).

Smith (2002) noted that the geology of the system was mapped by Chin (1986a, b). Sand plain and laterite occur at higher elevations while the valleys contain Holocene alluvium and Cenozoic sediments. The basement comprises medium to coarse adamellite, gneiss, rare dolerite, and quartz dykes some of which crop out as rocky knolls.

Today the Yilgarn and Lockhart Rivers merge at Caroline Gap to form a broad valley floor containing the Salt River and, further downstream, the Yenying Lakes. The two catchments comprise about 91,000 km² of mainly cleared agricultural land (WRC, 2002). Overflow occurs into the Avon River at Qualandary Crossing. The crossing was constructed in the early 1900s and acts as a weir to prevent backflow from the Avon River. The current gated culvert was completed in 1998; the gates are opened under moderate flows while flood events pass over the top of crossing (WRC, 2002).

A series of oblique color aerial photographs of the Yenying Lakes were available from ten low-level flights undertaken by one of us (JD), in different seasons, between October 2002 and May 2004. The photographs

were used to determine the patterns of inundation in the salt playas and across the Salt River valley floor, the shape of the playas and the degree of interconnectivity, and the presence and extent of retentive features, such as sandy banks and lunettes. Lunettes are the windblown ridges of fine sediment that often accumulate on the downwind margins of seasonally dry lakes due to deflation of the dry lake bed (Bowler, 1973). Remotely sensed imagery revealed the extent of inundation following a major episodic rain event throughout most of the catchment in January, 2000. A field visit which followed the Salt River, upstream, from Yenyening Lakes to Caroline Gap was undertaken in May 2004 to ground truth aspects of the aerial photographs.

A series of channels and playas of various sizes occur immediately upstream of Qualandary Crossing for a distance of approximately 30 km. Sandy or clay banks and “lunettes” are present. The lunettes are relatively bright on air photography; rise between 1 and 3 m above the dry season water level (DSWL – as noted in 2004) are arcuate in planform and usually are best developed on the downwind side of a given playa. The sandy banks, usually rising less than 2 m above the DSWL, often occur as a collection of several subparallel ridges that are particularly obvious at low water levels. Those within the lakes appear to be lunettes that formed during lower lake levels but have been submerged by a rise in the water level. Both the sandy banks and lunettes are actively developing as witnessed by blowing sand and the presence of recent wind ripples on their surfaces in 2004. However, the effects of river flow and wind-driven water circulation must also play a role in the formation and morphological evolution of these banks as often they are more linear in plan view than neighboring lunettes. Figure 2a reveals the presence of both banks and lunettes within lakes and channels throughout the system. A number of well-defined linear banks are present within The Channels and adjoining unnamed lakes (Figure 2b). The lower banks and lunettes are devoid of plant life or are dominated by samphires, but some of the higher ones, for example, those at Ossig’s Lake, contain shrubs and trees.

The pattern of bank and lunette formation evident at Ossig’s Lake under low water conditions, in March 2004, revealed the influence of both eolian and fluvial processes (Figure 3a). The direction of water flow is from bottom right to top left, the northeast, while the predominant wind direction in summer (Figure 3b) is from top left to bottom right, the southwest. Thus wind-driven mixing, acting against the direction of any residual river flow, will predominate during summer. High river flows will be in the same direction as the dominant winds (northeasterly) during winter. Further upstream the geomorphology of the valley floor changes to that of fewer and smaller pools and finally to a network of complex, shallow channels. It is likely that the rise in the saline water table has resulted in greater definition of the shallow, diffuse channels. Under previous, less waterlogged conditions, many of

these shallow channels may have been predominantly dry and would have supported low, terrestrial plant communities.

The evaporation from the shallow water table which concentrates the salts in groundwater near the surface and accumulates them in the soil, as described by Smith (2002), is demonstrated by the white areas of salt prominent on the valley floor margins in Figure 2b.

Under conditions of high flow, many of the banks are submerged; however, those banks and lunettes containing well-developed plant communities are likely to be rarely flooded. A field visit in May 2004 demonstrated that although many banks and lunettes are submerged during high river flows, their morphology should still exert a major control on the direction of water flow, mixing processes, and retention times. Whereas small banks tend to be approximately parallel to the direction of flow, high banks also occur that are transverse to the direction of stream flow. These few very high banks are stable features, with good soil development and relict woodland, and occur as breached barriers between successive major salt lakes. These banks appear to consist of amalgams of two or more “fossil” lunettes, developed on a scale in excess of the smaller, active lunettes within the lakes; they rise to around 20 m above the DSWL. In each case, a single channel cuts through each bank, thus connecting contiguous lakes. These high banks were not inundated by the exceptional flood of January 2000. This conclusion may be drawn from the evidence of water levels in the satellite images and also from wrack marks consisting of accumulations of shells of the gastropod *Coxiella*, which are around 2 m above the DSWL.

Large lunettes developed in SE Australia between 17,000 and 15,000 B.P. (Bowler, 1973). No dates are available for the Yenyening banks, but it is hypothesized that these fossil lunettes developed in the late Quaternary and/or Holocene and are evidence for seasonal desiccation of these chains of lakes, even if the water flow at that time was less saline. The presence of these large banks separating individual lakes affords a considerable degree of retention to water flow down through the system, both through constraining surface flow to a single connecting channel but also almost certainly inducing shallow groundwater seepage between adjacent lakes.

Small lunettes and the lake margins are visibly subject to wind action as wind-blown sand and eolian ripples were observed in 2004. Nevertheless there is no clear morphological relationship between the lunette and lake plan views and the prevailing wind direction. Thus a more detailed analysis of the orientation, morphology, stratigraphy, and sedimentology of the smaller lunettes and linear banks with respect to the prevailing winds is needed to fully elucidate the processes by which these structures have formed. Similarly the large wooded banks separating many of the lakes are one order of magnitude higher than the small active lunettes and of considerable bulk. These are hypothesized to be lunettes that formed under prior wind and hydrological regimes.

Playa Lake Chains: The Example of the Yenying Lakes of the Upper Avon River Catchment of Western Australia,
Figure 2 (a) *Right to left:* Racecourse Lake (dry with white salt crust), Ossig's Lake, The Neck, and Mud Lake (dry). Morbining Gully in the foreground. Direction of flow is from left to right. Oblique view from the northeast, December 22, 2003. (b) *The Channels.* Flow in this region is diffuse but overall direction is from left to right. Oblique view from the north, December 22, 2003.

Notwithstanding the lack of detailed data, the information revealed by aerial photography and ground survey is sufficient to indicate that the lunettes and banks are an important structural component of the Yenying Lakes system that records the history of lake and drainage network development as well as controlling modern-day retentiveness.

Evidence of freshwater seeps along the margins of the valley floor were also evident (through distinctive color changes) in some aerial photographs. The healthy plant communities present on the southwestern corner of The Channels indicated the presence of freshwater discharging from the adjacent slope. Whether this area will be

enhanced or degraded by the recent planting of maritime pines (*Pinus pinaster*) on the privately owned adjoining slope is not known. This area appeared to contain the best example of healthy vegetation within the entire reserve and deserves further investigation. Freshwater seeps were noted elsewhere using aerial photography and one, at Yenying Lake, had a considerable surface flow. These seeps are of considerable nature conservation value, have local agricultural value, and have a currently undefined effect on dilution of low-flow saline waters in the valley.

The dry, salt-encrusted states of two lakes (Racecourse Lake and Mud Lake) were found to be due to the diversion

Playa Lake Chains: The Example of the Yenying Lakes of the Upper Avon River Catchment of Western Australia,

of water undertaken by a local resident in an attempt to promote flow through the main system. This was undertaken with the expectation that such action would prevent an increase in the salt load in the large lakes used for recreational activities (water-skiing) (T. McLean, pers comm.). This approach to “disconnecting” some lakes from the rest of the hydraulic system to decrease the retention time of water in the rest of the reserve is an unproven technique that might have unforeseen repercussions on the

nutrient status of the water and the ecology of the lakes that remain connected.

Nature conservation, cultural, and recreational values

The nature conservation and recreational values of the lake were described by the Yenying Lakes Management Strategy (1996). The lakes are recognized as an important area for waterbird habitat and breeding, with 41 species

recorded using the lakes, and 10 species are known to breed there (YLMS, 1996). Forty-six land species have been recorded in the lakeside bushlands. The lakes are encompassed by two Nature Reserves; these are vested in the Conservation Commission of Western Australia and managed by the Department of Conservation and Land Management. The main series of lakes lies within Reserve 31837 which was created for the purposes of "Recreation and Conservation of Flora and Fauna." Further upstream is Reserve 28088 which was created for the "Conservation of Flora and Fauna" and contains The Channels and adjoining flats and banks (Yenyening Lakes Management Strategy, 1996).

The first sighting of the numbat (*Myrmecobius fasciatus*), a now rare and endangered marsupial, was recorded from the lakes' area by Ensign Dale (1831) in a letter to the Surveyor-General, J.S. Roe (Cross, 1833). Dale also noted the presence of "an inland lake of freshwater or perhaps a reservoir of the river"... "varied in its breadth from 60 to 70 yards, and 5 or 6 miles in length." Upon reaching this, he described seeing "an immense number of ducks, swans and other waterfowl" (Cross, 1833, p. 156).

The Yenyening Lakes Management Strategy (1996) noted that older local residents remembered the lakes teeming with birdlife and the surrounding woodlands supported native animals and wildflowers. The area was first settled in the 1890s, and degradation due to rising saline groundwaters was observed from the 1930s onward together with the spread of exotic weeds and the arrival of exotic fauna including rabbits, foxes, and feral cats. Although the bushland adjoining the lakes is now considered to be extremely degraded, the numerous sandy banks within the lakes' system appear to be unaffected by salinization, and although weedy, still support a range of local plant species including the salt-tolerant Salt River gum (*Eucalyptus sargentii*) and the Yenyening mallee (*E. vegrandis*). Seed is collected from *E. sargentii* for land rehabilitation programs throughout the southwest (Yenyening Lakes Management Strategy, 1996).

Ensign Dale noted that numerous aboriginal groups were seen in the area (Cross, 1833). Although little specific information appears to have been recorded, the presence of freshwater and abundant wildlife suggests that the lakes were important for indigenous groups.

Early settlers hunted, swam, and picnicked by the lakes, but the current most popular form of recreation at the lakes is water-skiing (Yenyening Lakes Management Strategy, 1996). As a consequence, some of the current management of water levels in the lakes, via the gates at Qualandary Crossing, is undertaken to maintain suitable water depths and water quality for skiing.

Interpretation of the aquatic ecology of the Yenyening Lakes and salt river system from aerial photography

Although the nature conservation values of the Yenyening Lakes are well recognized (Yenyening Lakes

Management Strategy, 1996; Water and Rivers Commission, 2002), little information exists on the aquatic ecology of the lakes. Recent work on the ecology of secondary saline wetlands in the Wheatbelt region by Davis et al. (2003) and Strehlow et al. (2005) suggested that three possible ecological regimes may exist in these systems: clear, macrophyte-dominated; turbid, phytoplankton-dominated; and clear, benthic microbial mat dominated.

The concept of two states, clear water dominated by aquatic macrophytes and turbid water dominated by phytoplankton, has been described in shallow European lakes undergoing eutrophication (Scheffer, 1998; Jeppesen et al., 1990; Blindow et al., 1993; Scheffer et al., 1993; Moss et al., 1996). Davis et al. (2003) extended this approach and identified contrasting aquatic vegetation states that were closely associated with different salinities. They suggested that salinization results in the dominance of a small number of salt-tolerant submerged aquatics (*Ruppia*, *Lepilaena*, *Chara*, and *Lamprothamnium*). With increasing salinity, these systems may undergo further change to microbial mat-dominated systems comprising mainly cyanobacteria and halophilic bacteria.

Because of the difficulties in demonstrating stability and the alternative nature of these states, Strehlow et al. (2005) suggested that the term "ecological regime" should be used *sensu* Scheffer and Carpenter (2003).

Sim et al. (2006a) suggested that the upper limit for submerged aquatics may be as high as 90 mgL⁻¹ TDS. Additionally, however, the submerged aquatics studied so far in Wheatbelt wetlands also appear to have a requirement for a seasonal water regime. Benthic microbial mats appeared to be dominant in seasonal waterbodies at salinities >90 mgL⁻¹ or at lower salinities if a permanent water regime is present. Positive feedback loops are likely to exist such that mats can outcompete (and overgrow) germinating seedlings under a permanent water regime. Conversely aquatics can germinate and seedlings quickly develop as a seasonal wetland refills, effectively disrupting the conditions needed for benthic mat development (Sim et al., 2006b).

An upper limit of salinity has not been determined for turbid, phytoplankton-dominated systems. Moss et al. (1996) suggested that this state is likely to dominate at concentrations of total phosphorus > 150 µgL⁻¹.

Aerial photography revealed the presence of both turbid, phytoplankton-dominated and clear, benthic microbial mat-dominated regimes in the Yenyening Lakes and Salt River system. The different colors present in pools in The Channels, under low-flow conditions, were most likely to have been produced by phytoplankton blooms or dense benthic microbial mats. Although the presence of phytoplankton and microbial mats can be established from aerial photography, accompanying field surveys are needed to determine species composition.

The presence of clear, macrophyte-dominated regimes was not easily determined from the aerial photography available; however, the field visit made to Ossig's Lake in May 2004 revealed the presence of extensive dead mats of *Lamprothamnium* sp. and some live material. This suggested that conditions were suitable for the development of a clear, macrophyte-dominated regime in at least some of the lakes within the system. Stands of macrophytes provide a direct source of food for herbivores such as swans and habitat for invertebrates which, in turn, provide food for ducks and waders.

Conceptual model of the interaction between hydrology, geomorphology, and ecology in the Yenyening Lakes and salt river system

The complex pattern of lunettes, linear banks, mounds, and shallow channels present within the Yenyening Lakes system suggests that the retention time of water within the system is likely to be high under low to moderate flows. The exception would be the infrequent, episodic, very high flows such as those recorded in January 2000. The highly seasonal climatic regime of the region (cool, wet winters and hot, dry summers) also indicates that most of the shallow lakes would undergo extensive summer drying in low and average rainfall years. However, the present complex drainage network ensures that lakes dry to differing degrees, as indicated by different water levels in different lakes induced by retentiveness. Thus the present drainage network maintains a major degree of physical and ecological diversity even in its degraded state.

The high retention times produced by the complex within-lake and channel geomorphologies combined with shallow, seasonal water regimes indicate that conditions are likely to be suitable for high rates of benthic and water column primary production in these systems. Prior to the land clearing associated with European settlement, this system would have supported a rich freshwater ecosystem probably dominated by submerged aquatics. This system would have supported the prolific birdlife of ducks and swans described by the early explorers (Cross, 1833). The increase in salinity, water depths, and nutrients that accompanied clearing and subsequent cropping would have moved the aquatic system in the direction of dominance by phytoplankton or benthic mats. However, the presence of submerged aquatics at Ossig's Lake indicates that the salinity levels and water regimes are not so disrupted that an irreversible shift in ecological regime has occurred. Although it is unlikely that these waterbodies will ever be restored to a fresher state, their current diversity needs to be recognized and protected.

POOPÓ LAKE, BOLIVIA

Lars Bengtsson

Department of Water Resources Engineering, Lund University, Lund, Sweden

Description

Lake Poopó is located on the Bolivian high plains at 3,700 m above the sea level. The lake is part of the TDPS system (Lake Titicaca, the Desaguadero River, Lake Poopó, and the Salares (Salt Flats), [Figure 1](#)) forming an extensive endorheic basin. Lake Titicaca is the highest situated of the world's large lakes. The Desaguadero River links Lake Titicaca with the downstream Lake Poopó. Lake Poopó is an extremely shallow lake with a mean depth of less than 2 m below the outlet sill level. At spill-over level the lake surface is very large and exceeds 3,000 km². However, since it is so shallow, the lake may in very dry periods dry out. In the present-day climate, there is very seldom any outflow from the lake, which means that the water level and thus the surface area are highly variable. The lake is in principle a terminal lake. The water is salty. The character of the lake is illustrated in [Figure 2](#), which shows the flat shores.

Next to Lake Poopó is also Lake Uru-Uru. The Desaguadero River divides into two river arms, one branch into Lake Poopó and another into Lake Uru-Uru. Lake Uru-Uru spills over into Lake Poopó. Lake Uru-Uru dries out every year. Its maximum depth is 1 m, when the surface area is 300–400 km². Prior to 1985 the Desaguadero River ran through Lake Uru-Uru before entering into Lake Poopó itself. At high water levels the two lakes constitute one single lake.

The Salinas, two huge salt accumulations from old lakes, Salar de Coipasa and Salar de Uyuni, are south of and downstream Lake Poopó. Enormous changes have taken place of the hydrology of the Bolivian Altiplano. Several lacustrine layers have been found in the sediments from the Salares. During the Tauca period (26,000–15,000 BP), the lower part of the Altiplano constituted a large single lake basin, Lake Tauca. In a drier climate this lake developed into three lake basins, Lake Poopó and the two Salinas, of which today the Salinas are salt accumulations.

Today Lake Poopó can be considered to be a closed lake rarely having any outflow. Last time there was outflow from the lake was in the mid 1980s. In early 2001 the lake almost reached its sill level. The lake seems to have been dry between 1939 and 1944 and almost dry in the early 1970s and again in 1994–1996. In a normal year the lake area varies between about 2,000 km² in March at the end of the wet period and 1,000 km² in November at the end of the dry period. The variation of the lake surface area over 50 years is shown in [Figure 3](#). As can be seen, there is a close relation to the water level of Lake Titicaca.

Poopó Lake, Bolivia, Figure 2 The shores of Lake Poopó (Photo Lars Bengtsson).

Also since the lake is a terminal lake, it means that not only salt but all sorts of pollutants are trapped in the lake. On the mountain slopes at the eastern side of Lake Poopó, mine activities have been going on for centuries. There are leakage of water very high in heavy metals from mining ponds and even more leakage from abandoned old mines. The high content of metals is visible from the color of the water and the sediments in some of the small rivers flowing into Lake Poopó. In spite of poor environmental conditions, indigenous poor people living on the lake shores still get their income from fishing.

The water balance of Lake Poopó is much determined by the Desaguadero River flow. The flow from this river constitutes almost 70% of the water input to the lake, while the contribution from regional rivers is only

Poopó Lake, Bolivia, Figure 3 Computed and observed (from satellite images and water stage) lake area of Lake Poopó (Drawn from data presented by Pillco and Bengtsson, 2006a).

10–15%. Precipitation on the lakes, 370 mm per year nonuniformly distributed, is about 20% of the water input. The water loss from evaporation is about 1,800 mm.

RESERVOIR AND LAKE TRAP EFFICIENCY

S. W. Trimble¹, B. Wilson²

Introduction

All streams transport sediment, and some of this sediment will be deposited in the relatively quieter waters of lakes and reservoirs (Morris and Fan, 1997). This accumulated sediment is detrimental to the lake or reservoir because it displaces the storage of water and often reduces the surface area. It is especially problematic in reservoirs designed for hydropower production: as useful storage volume is lost, increasingly only the flow of the river is available, and this may be insufficient during low-flow periods. In areas of extremely high sediment yields, smaller lakes and reservoirs may fill completely, but this is relatively rare. For some regions, reservoir sedimentation is no longer seen as a major problem. Indeed, in the USA, reservoir sedimentation surveys are now rarely performed.

Basic processes

As the sediment-laden stream flows into the relatively quiescent pool, the coarser particles are more rapidly deposited, while the finer particles are transported farther into the reservoir depending on the velocity and dynamics of the water. In some cases, especially where there is a sub-crest outlet at the dam, a sediment-laden flow termed a turbidity current, made denser by the sediment or by thermal conditions, can transport fine sediment into the deeper portions of the pool and, on occasion, even through the sub-crest dam outlet. Indeed, some dams are designed and operated with this phenomenon in mind.

Sediment, and particularly coarse material, may also accumulate above normal pool level or crest level upstream of the reservoir or lake. This happens when the inflowing sediment forms a delta out into the pool. Because a stream must maintain a slope or gradient to furnish energy to flow, the slope must be extended upstream of the pool by aggrading or building up its bed with sediment. This process not only raises the elevation of the river but can also permanently flood the areas adjacent to the stream. Perhaps the most famous example is upstream of Elephant Butte Dam, completed in 1916 on the Rio Grande River in New Mexico. Located 2 km upstream of the reservoir pool and several meters above it, the small town of San Marcial was partially flooded and eventually evacuated by the 1930s (Eakin and Brown, 1939). This above-crest sediment creates a wedge and may extend many kilometers upstream.

The trapping of sediment by reservoirs and lakes can create a sediment deficiency downstream. That is, stream flow deprived of its normal sediment load becomes “hungry” and tends to erode available sediment in streambeds downstream of the dam. In some cases, streams have cut vertically or “degraded” several meters over reaches up to several kilometers downstream of dams, often destabilizing banks and leaving water intakes stranded above water level (Williams and Wolman, 1984).

While most perceive reservoir and lake sedimentation in negative terms, there are also positive aspects. One of these is that with at least part of the sediment having been removed, the water available at the downstream end of the pool may be clearer. Another advantage is that an opportunity is provided to measure sediment yield. The conventional way of measuring sediment in stream by sampling is a very imprecise and problematic process. This is (a) because much of the sediment load is carried near the streambed and often goes unsampled, a very serious problem in some streams, and (b) the stream must be sampled

over long periods of time, a difficult and expensive undertaking. Thus, the importance of pools is due to the fact that they (1) intercept all events, not just the ones convenient to measure and (2) intercept bedload, the portion of sediment yield normally not measured. Thus, lakes and reservoirs have the potential to give much more realistic measurements of sediment yields of streams. Such measurements have been used to estimate sediment yield and fluvial processes over historical periods (e.g., Trimble and Carey, 1990; Butcher et al., 1992; McManus and Duck, 1993; Dearing et al., 1990; Foster, 1995; White et al., 1996).

Trap efficiency

Not all of the sediment transported by the stream is trapped because much can be transported over and through the dam (Verstreten and Poesen, 2000). The proportion of stream load trapped over any time period is termed trap efficiency (TE) and is a function of the kinetic energy within the reservoir and the type of sediment. Heinemann (1981) stated that TE is the single most informative attribute of a reservoir. The TE is important because, assuming the mean sediment yield (SY) is known, it allows planning for the longevity of the lake or reservoir. And with measurements of the sediment accumulation over time, SY may be estimated by adjusting the accumulation by the trap efficiency. Thus, if the measured accumulation is 1,000 t/year and the TE is 50%, the SY is actually 2,000 t/year. Normally, mean SY is expressed as tons per unit area (e.g., 50 t/ha/year), known as unit SY.

Long-term trap efficiency

Since reservoirs are long-term investments, the long-term consequences of sedimentation have generally been of greater interest, and the same is true of sediment yields; thus, the development of long-term TE has been a priority. Additionally, the long-term data required have been systematically gathered since the early twentieth century, particularly in the USA. That is, many reservoirs were

given systematic hydrographic surveys which were repeated every few years, and compendia were published giving the results (e.g., Dendy and Champion, 1975). With the use of these data plus stream load data and empirical surrogates of kinetic energy in lakes and reservoirs, researchers sought to come up with reliable estimates of TE.

Brune model. One of the oldest and certainly the most used model is that of Brune who used data from 40 large, normally ponded reservoirs (1953, Figure 1). The independent variable or basic predictor is the ratio of pool capacity (volume, termed C) to volume of annual stream inflow (termed I). The C/I ratio is also called the period of retention because the number suggests the number of years. The pool dynamic here is annual turnover, with a C/I ratio of 1.00 meaning that the pool content theoretically is drained and refilled every year, the measure suggesting a relative measure of kinetic energy. The C/I ratio is also called the period of retention. Note that there is a median curve predicting TE for most common values of C/I, but it is flanked by curves more appropriate for coarser or finer sediment. Since C and I values are almost universally available and the model is very easy to understand and use, it has become by far the most commonly used model to predict TE (USDA-SCS, 1983).

The Brune model was devised using data from large reservoirs, and it was later found that it did not predict as well for smaller reservoirs and lakes. Thus, a similar model was devised for smaller reservoirs and ponds by Heinemann (1981) which has also found wide acceptance.

The Churchill model. As early as 1948, Churchill suggested a model much more sophisticated than the Brune model just discussed (Figure 2). Its independent variable or predictor was termed the *sedimentation index* defined as the period of retention (Brune's C/I index) divided by the mean flow velocity through the reservoir. Because very few measurements of the latter are available, the usual working definition is the average inflow volume divided by the average reservoir or pond cross-sectional

Reservoir and Lake Trap Efficiency, Figure 1 An updated version of the Brune model. From USDA-SCS 1983.

Reservoir and Lake Trap Efficiency, Figure 2 The Brune model with revisions by Trimble and Bube. (Redrawn from Trimble and Bube, 1990.)

area. In any case, the sedimentation index is a much better surrogate of kinetic energy in a reservoir than the Brune C/I index. The other strong suit of the Churchill model was that it distinguished between sediment produced within the local catchment (local sediment, presumed to be coarser) and that conveyed downstream through upstream reservoirs (overflow sediment, presumed to be finer). The problem with acceptance of the Churchill model was that it was based on only a few data points and that it appeared in a short discussion in a somewhat obscure source.

But some saw the potential in the Churchill model, and Borland revisited it in 1971 adding some data and giving the model more visibility. Bube and Trimble (1986) and Trimble and Carey (1990) refined the model and used it to advantage in comparative studies with the Brune model. Trimble and Bube (1990) used a very large data set (a cascading system of 27 reservoirs over about 40 years) to further refine the Churchill model (Figure 2). Sediment was cascaded through the system in a simulation, and variance was minimized to optimize the TE values for both local and overflow sediment.

Physically based approaches

Estimating the trap efficiencies of individual runoff events is important for ponds built to reduce sediment yield from construction and other land disturbing activities. Trap efficiencies obtained from long-term studies are often inadequate for this type of assessment. Physically based approaches are widely used to capture localized site and watershed characteristics. These approaches are also appropriate in computing the trap efficiencies of small lakes and reservoirs.

Physically based approaches are dependent on the influent sediment characteristics and on the hydraulic response and geometry characteristics of the reservoir. The most important characteristic of influent sediment is the particle size distribution. Large particles are obviously easier to trap than small ones. Inflow and outflow

hydrographs are often used to estimate the hydraulic response of the reservoir. The outflow hydrograph can be computed using reservoir routing techniques (Haan et al., 1994). Although these techniques are straightforward, calculations can be tedious. Most physically based approaches are therefore computer programs that include reservoir routing computations as part of the analysis. Surface area as a function of elevation is an important relationship to characterize basin geometry and is necessary to perform reservoir routing. This relationship can also be used to estimate the fall distance for trapping of particles and, in more rigorous models, to determine hydraulic properties necessary for computing scour and turbulent characteristics.

Insight into the role of particle size, hydraulic response and basin geometry can be obtained by using overflow rate methods (Camp, 1946). Overflow rate methods were originally developed for sedimentation basins of wastewater treatment plants. Let's consider the idealized basin of constant depth shown in Figure 3. The idealized basin assumes steady flow with no mixing (plug flow assumption) among previous inflows, uniform vertical distribution of sediment at the inlet, no turbulence, and no resuspension of bed particles. There exists a particle diameter, d_c , that will fall the entire depth (h) within the time it takes to travel between the inlet and outlet. This time is called the detention time (t_d) and, for the idealized basin, corresponds to the time required to displace the basin volume (WLh) by the steady state flow (Q). The settling velocity (ω_c) corresponding to d_c is then defined as

$$\omega_c = \frac{h}{t_d} = \frac{Q}{A_s} \quad (1)$$

where A_s is the surface area of the basin (WL), and the detention time is obtained by dividing the volume by the flow rate.

The relationship of Q/A_s is called the overflow rate and is a function of basin hydraulics and geometry. By using Stokes equation or other settling velocity relationships,

Reservoir and Lake Trap Efficiency, Figure 3 Idealized basin for overflow rate methods.

the critical diameter corresponding to ω_c (as computed using Equation 1) can be computed (Haan et al., 1994). For the idealized basin of Figure 3, all particles larger than this diameter are trapped. The fraction of the total mass for these particles is defined from the particle size distribution. This concept is also shown in Figure 3 where “ $1 - F_c$ ” is the fraction of mass greater than d_c .

In addition to particles that settle the entire depth, smaller particles located closer to the bed will also be trapped. For the idealized rectangular basin, the trapping of these particles is proportional to the ratio of their settling velocities to the critical velocity. The overall trap efficiency of sediment using the overflow rate approach is then defined as

$$E = (1 - F_c) + \sum_{i=1}^n \left(\frac{\omega_i}{\omega_c} \right) \Delta F_i \quad (2)$$

$$= (1 - F_c) + \sum_{i=1}^n r_i \Delta F_i$$

where E is the trap efficiency, n is the number of class sizes of sediment with diameters (d_i) smaller than d_c , and ω_i and ΔF_i are the settling velocity and fraction of mass corresponding to d_i . A conceptual representation of the terms in Equation 2 is shown in Figure 3 for the case where $n = 4$. The ratio ω_i/ω_c is often called the Hazen number. For the idealized basin, it corresponds to the fraction of particles (r_i) of diameter d_i that are trapped.

Extensions are needed to the overflow rate methods to predict trap efficiencies of irregularly shaped lakes and reservoirs with unsteady flows. However, before discussing these extensions, let's consider less restrictive conditions for the idealized basin of Figure 3. Detention time in Equation 1 is computed by displacing the entire basin volume with flow. Often a fraction of the basin volume is effectively isolated from the flow patterns. This isolated volume is called dead space. Camp's trap efficiency approach is easily modified for dead space by

simply decreasing the detention time to correspond to a smaller volume displaced by flow. The revised detention time is simply computed as $WLh(1 - f_d)/Q$, where f_d is the fraction of dead space.

Since some mixing of flows occurs within the basin, much research has been done to remove the assumption of plug flow. Simple reactor models provide a framework for representing non-plug flow characteristics. Reactor models are developed by dividing the basin into chambers or reactors in which either plug flow or completely mixed flow can occur (Wolf and Resnick, 1963; Cooper and Jefferys, 1971). Separate mass balances are used for each reactor. The level of mixing can be controlled by increasing or decreasing the number of reactors. Plug flow corresponds to the special case of an infinite number of reactors. Chemical dyes can be used to determine the appropriate reactor configuration. Griffin et al. (1985) provide results that can be used to estimate the number of completely mixed reactors and the fraction of dead space for lake and small reservoirs.

The impact of turbulence on the trapping of particles was investigated by Dobbins and Camp as early as 1944. Dobbins solved a mass balance for one-dimensional flow in rectangular basin using a turbulent diffusion coefficient that is independent of depth. His solution is a function of the previously given Hazen number (i.e., ω_i/ω_c) and the sedimentation Peclet number. The sedimentation Peclet number is a measure of the relative movement of sediment by settling to that by turbulent diffusion. Hence, large Peclet numbers correspond to conditions where the relative movement of sediment by turbulence is small.

The impact of turbulence on the removal fraction of particles of size d_i (r_i) is shown in Figure 4. The solution for r_i with no turbulence, as originally formulated in Equation 2, is given by the one-to-one line in this figure. As turbulence increases, the Peclet number decreases, and the removal fraction of particles also decreases. For example, all particles are trapped for Hazen number of one with no turbulence. The removal fraction is reduced

Reservoir and Lake Trap Efficiency, Figure 4 Impact of turbulence on trapping of particles.

to roughly 0.9 and 0.7 for Peclet number of 10 and 1, respectively. The exponential relationship for r_i proposed by Chen (1975) for highly turbulent conditions corresponds closely to the solution of a Peclet number of one tenth. As shown by Figure 4, all particles are no longer trapped for diameters greater than d_c with turbulence. Therefore, the “ $1-F_c$ ” term in the trap efficiency given by Equation 2 is no longer appropriate. Equation 2 is easily modified for turbulence by removing “ $1-F_c$ ” and by including additional diameters greater than d_c in the summation term (Haan et al., 1994).

As an alternative to reactor models, hydraulic flow characteristics can also be predicted using basic hydrodynamic relationships. Here the movement of fluid and sediment is predicted by coupling conservation of mass relationships with an equation(s) of motion. An important theoretical challenge with this approach is the representation of fine time and length scales necessary to represent turbulence. Time or space averaging techniques are therefore used, but these techniques introduce additional stress terms (Pope, 2000). Although the determination of constitutive relationships for these stress terms has received much attention, more work is needed for the complex flow patterns in lakes and reservoirs. Hydrodynamic relationships can be formulated for three-dimensional problems. Two-dimensional depth-averaged solutions have also been proposed to reduce computational requirements (Rastogi and Rodi, 1978).

Physically based models

The overflow rate concepts of the previous section have been modified to predict trap efficiencies of irregularly shaped lakes and reservoirs. A simple approach is the EPA method (see Haan et al., 1994) where the flow rate is defined using the peak outflow rate and the surface area is defined as that area corresponding to the crest of the outlet riser. The overflow rate is increased by a factor of 1.2 to

account for nonideal characteristics. This overflow rate is assumed to be constant for all inflows. Tapp et al. (1981) extended the EPA method to vary the overflow rate with time. They proposed two methods. One method uses time-varying outflows to compute overflow rates; the other method uses both outflows and fall depths to determine time-varying overflow rates. These simple extensions are, at best, modestly effective. They oversimplify complex processes.

Ward et al. (1977, 1979) developed a comprehensive pond simulation model called DEPOSITS (Detention Performance Of Sediment In Trap Structures). The DEPOSITS model assumes plug flow. However, in contrast to the overflow rate methods, the critical settling velocity is obtained directly from the fall depth-detention time ratio of Equation 1 (i.e., h/t_d) and not the overflow rate itself. A detention time is computed for each inflow plug entering the reservoir or lake. The time corresponding to the discharge of the plug is computed from a cumulative outflow volume curve. This concept is shown in Figure 5. The first inflow plug is the first outflow plug discharged after the permanent pool is “pushed” out of the basin. The average fall distance for particles is computed using a volume-weighted depth corresponding to the time that the sediment is in the reservoir or lake. The DEPOSITS model has been shown to have good accuracy in predicting observed trap efficiencies, but can have problems in predicting the observed effluent concentrations (Ward et al., 1977, 1981; Wilson and Barfield, 1981).

The inability of the DEPOSITS model to predict accurately observed effluent concentrations is likely caused by the limitations of assuming plug flow. To allow mixing between inflows and the permanent pool volume, while maintaining a relatively simple computational framework, Wilson and Barfield (1984) developed the CSTRS model. With this model, the reservoir is divided into reactors or

Reservoir and Lake Trap Efficiency, Figure 5 Computation of detention time for plug flow models with unsteady flow.

Reservoir and Lake Trap Efficiency, Figure 6 Representation of flow processes in the BASIN model.

chambers of equal volume. A mass balance is then maintained for each reactor. A critically important component of this mass balance is the deposition within a time step. In contrast to the plug flow model of DEPOSITS, where a single detention time can be used for each inflow volume shown in Figure 5, the sediment in the CSTRS model mixes with other sediment from previous inflows and, therefore, cannot be represented by a single detention time. Some particles remain in the reservoir for a long time, whereas others are discharged almost immediately. This variation in residence time is estimated using idealized deposition processes in the reservoir and identifying simple trends of depositional patterns with time. A comparison of predicted and observed results with the DEPOSITS and CSTRS model showed relatively small differences in trap efficiencies (Wilson and Barfield, 1984). However, the CSTRS model was superior in

predicting the observed effluent concentrations. The DEPOSITS and CSTRS models are both options in the SEDIMOT II (Wilson et al., 1984) and SEDCAD (Schwab and Warner, 1996) watershed models for computing trap efficiencies in small reservoirs.

Although the CSTRS model is an improvement in representing flows within reservoirs and lakes, it is still limited by not considering the impact of turbulence and bed scour and resuspension. The BASIN (Basin Analysis of Sediment-laden INflow) model was developed by Wilson and Barfield (1985) to account for these processes in the prediction of trap efficiencies. The BASIN model also divides the ponds into a number of reactors. By assuming mixing within the reactor in only the non-vertical directions, a sediment balance can be easily derived for infinitesimally layer, as shown in Figure 6. This sediment balance is then solved using an efficient

numerical algorithm. Turbulent diffusion coefficients are required to simulate the impact of turbulence. Bed scour calculations are required to establish the lower boundary condition. Oolman and Wilson (2003) modified the BASIN model to allow the turbulent diffusion coefficient to predict directly in the model using the theory presented by Wilson and Barfield (1986) and to utilize the detachment algorithm developed by Wilson (1993).

Hydrodynamics models are the most rigorous approach to represent flow processes in lakes and small reservoirs. Kersten (1963) used jet theory to represent the hydraulic characteristics of flow at the reservoir's inlet and then solved the mass balance equation for sediment using finite difference techniques. Kuo (1976) further expanded upon this work by assuming the flow is symmetrical between the inlet and outlet. Chen et al. (1978) used a depth-averaged form of the mass balance for sediment and water and an equation of motion. The reservoir is divided into "subchannels," and lateral flow is used to have flow between these subchannels. More recently, Kennedy et al. (2006) used a three-dimensional hydrodynamic model to determine the hydraulic retention time of flows in reservoir. A tetrahedral mesh of more than 1.6 million cells was used to represent the basin bathymetry and inlet and outlet conditions.

RESERVOIR CAPACITY

Reginald Herschy
 Hydrology Consultant, Reading, UK

Introduction

During high river flows, water has to be stored so that a uniform supply of water can be assured for supply for drinking, irrigation, power generation, and other needs during periods of low river flows.

Hydrological investigations are necessary for the design of a reservoir in consideration of the following:

1. Quantity of water available
2. Quality of the source
3. Construction
4. Suitability of the dam
5. Distance from the source to the customer
6. Elevation of the reservoir
7. Safeguard of quality
8. Topographic survey
9. Geological survey
10. Appraisal of necessary land use
11. Cost of the scheme

The estimation of the quantity of water which the reservoir will yield is the first consideration, and it is necessary to make estimates of the yield in relation to the amount of storage and capacity the reservoir will hold. The yield of a reservoir is the volume of water regularly available over a unit period of time.

Methods used for estimating capacity

The following methods may be used for estimating capacity: (1) the graphical method and (2) the numerical method.

1. Graphical method

Figure 1 shows an example of a mass curve to determine the storage capacity of a reservoir. Plots of the cumulative sums I and D represent the inflow and outflow draft mass curves, respectively, with S the initial reservoir storage. It can be seen that the reservoir storage capacity is the difference between the input and output mass curves. In Figure 1 the reservoir storage S is determined for a constant draft D with the constraint that no failure is allowed during the design period. The procedure employs the concept of a semi-infinite (bottomless) reservoir and yields the required storage capacity as the minimum storage depletion recorded in an initially full reservoir during the design period. The constant draft corresponds to a constant slope of the draft mass curve D. A line parallel to D is drawn through each peak on the inflow mass curve I. The design storage capacity S is the maximum vertical distance between any point on I and any of the lines that are parallel to D.

2. Numerical method

The numerical method for the estimate of storage is a mass balance between water entering a reservoir (precipitation, streamflow). The equation is:

$$S_i = S_{i-1} + I_i + P_i - E_i - D_i - O_i \\ = S_{i-1} + \Delta S_i \quad (1)$$

where S_i is the storage capacity at the end of time interval i , S_{i-1} is the storage at the beginning of time interval i , I_i is the inflow during interval i , E_i is the evaporation during interval i , D_i is the draft or abstraction during interval i , O_i is the outflow or spillage during interval i , and ΔS_i is the change in storage during interval i .

Other computerized methods that aid computation analysis are available especially in the design and operation of multipurpose reservoirs requiring complex analysis normally carried out by iterative methods.

Where storage needs to be determined to maintain a certain draft, Equation (1) is solved for different assumed maximum storage capacities (S) to find, in an iterative manner, the capacity where the reservoir is drawn down to almost empty, or the minimum operating level. Where a dam already exists or the storage is fixed, the abstraction rate which can be maintained can be determined by

Reservoir Capacity, Figure 1 Mass curve approach for the determination of storage capacity S required for supplying constant draft D (Note: This figure is reproduced with the kind permission of WMO).

substituting storage with draft as the variable in the equation. The sequence of levels of reservoir storage which result from solving Equation 1 is referred to as the storage trajectory.

The trajectory will generally be bounded by the full and minimum operating level states. In general, the trajectory for a given inflow sequence and abstraction rate will be a function of the starting storage level and will differ from starting level to starting level. However, once corresponding full or minimum operating level states have been reached for the range of starting storages, the trajectories from that point onward will be indistinguishable for a given inflow sequence and abstraction rate.

The period of maximum drawdown of a reservoir, that is, from a full state of storage down to the minimum operating level and recovering until it reaches the full level again, is referred to as the critical period. To reach stability in the analyses, it is important that the critical period be clearly defined by the reservoir trajectory.

Computing power has increased significantly, facilitating the solution to Equation 1, and reservoir design has been improved by the digital approach, offering greater flexibility in analyzing various scenarios of the storage-yield relation.

Remote sensing estimates of reservoir capacity

Digital multispectral data can be used for delineation of surface water bodies including lakes, reservoirs, and ponds. These data can be subjected to automated analysis and meet accuracy requirements. Satellite data provide to determine morphometric parameters such as length,

width, and surface area for different elevations depending on the satellite resolution.

From a remote sensing perspective, water has a low reflectance especially in both the near-infrared and visible portions of the electromagnetic spectrum. Remote sensing can really only determine the surface of the water and not measure volume of water in storage directly in reservoirs. For this purpose a relation between reservoir water stage and volume is prepared.

Climate change and its effect on storage

There is evidence that global temperatures are rising, and the rate of increase may be significantly higher than has occurred in the past. Models suggest that this could cause change in precipitation and increase the variability of climate, and streamflow could decrease by the year 2015.

Such changes would have significant impacts on yield and on the water resource systems.

In storage design scenarios, it is appropriate to consider any impact of climate change during the life of the reservoir.

The effect of floods on storage

The storage to be provided to retain flood waters in a reservoir depends on the volume, peak flow, and expected duration of the flood. Because floods may occur at any time during a season, reservoirs may have to be designed to have a storage capacity to allow for floods and can sometimes be designed as either onstream or off-stream reservoirs.

Flood detention storage is often provided in multipurpose onstream reservoirs with a facility to provide a high degree of control.

In multipurpose reservoirs, storage has often to make provision for other interests such as irrigation and hydro-power as well as flood control, and sometimes these interests compete with each other. This is especially the case when more than one country is involved.

The storage required in multipurpose reservoirs, therefore, requires a compromise to realize the maximum benefits.

The effect of drought on storage

In studying yield of a catchment, the variability of runoff is considered, and, in this case, yield may be defined as the uniform rate at which water can be drawn from the reservoir throughout a dry period of specific severity without depleting the contents to such an extent that withdrawal at the rate is no longer feasible. So given a fixed storage capacity in the reservoir, over a drought period of greater severity than that of the design, the regular amount of water available for supply, yield would have to be reduced. The occurrence of any such drought governs the yield for a given storage. Alternatively, if a constant yield is required beyond the capabilities of a reservoir designed to fulfill requirements over a drought of specified severity and duration, the capacity of the storage would need to be increased to meet the demand. To ensure adequate storage for a constant yield or to evaluate the yield of an existing reservoir, the study of low river flows is crucial.

Computing power has increased significantly, facilitating the solution to [equation \(1\)](#), and reservoir design has been improved by the digital approach, offering greater flexibility in analyzing various scenarios of the storage-yield relation.

RESERVOIR SEDIMENTATION

Bijan Dargahi

Division of Hydraulic Engineering, Department of Land and Water Resources Engineering, Royal Institute of Technology (KTH), Stockholm, Sweden

Introduction

Reservoir sedimentation is the gradual accumulation of the incoming sediment load from a river. This accumulation is a serious problem in many parts of the world and has severe consequences for water management, flood control, and production of energy. The worldwide loss in reservoir storage capacity is reported to be between 0.5% and 1.0% per annum (White, 2000). The gradual process of sedimentation proceeds with different speeds that depend on a large number of factors, such as hydrology of the catchments and the characteristics of the river basin. Sediment will eventually fill a reservoir within 50–200 years. Here, the crucial point is the fact that reservoir sedimentation is just a symptom of erosion of the topsoil. The principal causes are anthropogenic activities such as deforestation, and overgrazing. The complexity of the problem increases when the anthropogenic activities interact with natural changes imposed by the dynamic nature of climate and the earth surface processes. It is reported that 30% of the world's arable land has become unproductive during the past 40 years (Center for Earth Leadership, 2010). The same source reports that 65% of the earth's top soils are already degraded. An intriguing article published by *National Geographic* in the September 2008 issue (Mann, 2008) explores different aspects of soil erosion and the role of traditional methods for its mitigation. Mann states that only 3% of the earth's surface can be cultivated in soils

that are only 20 cm thick. The exception is the very limited regions of terra preta, or “black earth,” mainly found in Brazil’s Amazon Basin where the soil thickness is about 2 m. The point here is to emphasize two important aspects. One of the starting points for understanding and analyzing reservoir sedimentations is the understanding of soil erosion. Second, a mitigation plan is only effective if it includes soil conservation measures. Achievement of the task requires careful consideration of three interrelated areas:

1. The source of sedimentation and the processes involved
2. Modeling of erosion and sedimentation processes
3. Mitigation measures and their effectiveness

Figure 1 shows a general schematized chart of reservoir sedimentation sources and different modeling approaches. The source of reservoir sedimentation should be seen in relation to its cause. Here, it is instructive to consider the available lessons on the reasons for sedimentation of reservoirs. An important reason appears to be the failure in considering the reservoir as an integrated part of the river basin (Chanson and James, 1998). Bowonder et al. (1985) gave a number of specific reasons for sedimentation in reservoirs in India. Among these are land use policy, the absence of land use regulations, poor monitoring systems, lack of awareness of soil erosion and the value of soil conservation measures, emphasis on short-term gains, poor coordination of activities, and the lack of a trained

Reservoir Sedimentation, Figure 1 A schematic of reservoir sedimentation source and modeling.

workforce. The author recognizes the socioeconomic aspects as a central issue that probably would apply to many regions in the world.

Sediment is often both dissolved and solid with non-cohesive and cohesive properties. Dissolved loads are products of chemical weathering, and solid loads are delivered from the basins into the rivers through the action of rock weathering (Nichols, 2009). The quantity and type of sediment depend on the geology, topographic character, climate, vegetation type, and land use within the drainage basin. Sediment yield worldwide varies from one to more than 1,000 t/km²/year. In the lower range are desert regions and in the upper range are large mountain belts (Jansson, 1988). Extreme high yields in the range 10,000–50,000 are reported for basins in China, Java, Kenya, New Guinea, and New Zealand (Walling, 1994).

The subject of reservoir sedimentation has been thoroughly investigated and researched. The author has located over 350 journal papers among which are several useful handbooks and guidelines that deal with general sedimentation aspects, sediment yield, and mitigation methods. Some of main contributions are as follows:

1. An extensive review of methods to compute reservoir sedimentation is given by Bruk (1985) on the initiatives of UNESCO. The review is particularly interesting as many case studies as well as practical applications are included.
2. Morris and Fan (1997) give a comprehensive treatment of the subject area in a handbook of reservoir sedimentation. The US Army Corps of Engineers (1997) published a short summary of hydrological requirements for reservoirs. The manual was intended to serve as guidance to field office personnel for hydrologic engineering investigations for the planning and design of reservoir projects.
3. The details of the sedimentation processes and their control are summarized in a manual of reservoir silting and desilting (Batuca and Jordaan, 2000).
4. Xiaoqing's manual (2003) on sediment management provides a comprehensive revision of different aspects of sediment transport and its management. Ecological and environmental aspects are highlighted. Useful methods are outlined for computing soil erosion and sediment transport in rivers. A set of empirical equations are listed for estimating reservoir sedimentation characteristics.
5. On the initiative of the World Bank, a computer model RESCON 2003 (REServoir CONservation) was developed for the economic evaluation of sediment management. The key algorithm of the model is an economic optimization function that helps to quantify basic parameters. The model can be used to assess the technical and economic feasibility of implementing the life cycle management approach development.
6. A practical design manual, published by HR Wallingford as a guideline for predicting and minimizing sedimentation in small dams (DFID, 2004), provides useful procedures for predicting soil erosion, sediment yield, and the sedimentation rate in small reservoirs. The manual includes several worked examples that serve to illustrate the methods to the reader.
7. A large number of excellent articles are assembled in a technical document published by UNESCO in its Hydrology Series (Summer and Walling, 2002). The articles address various issues in modeling erosion. The document also includes two valuable sections on the comparison of different erosion and transport models.
8. Reservoir sedimentation, monitoring, and management were the theme of the sixth Federal Interagency Sedimentation Conferences. The proceeding was compiled in two volumes that included many topics on erosion control, river channel morphology, sediment transport, watersheds, and different modeling approaches (FISC, 2006).

Several interesting cases studies are also available that can serve as valuable sources of information (Atkinson, 1996; Morris and Fan, 1997; Chanson and James, 1998; de Oliveira Carvalho et al., 2000; Althaus and Cesare, 2006; Muller and Cesare, 2009).

River response to dam construction

Sediment is continuously supplied to rivers primarily through the process of surface erosion. Reservoir sedimentation is a fluvial process resulting from intercepting the natural flow of a river by constructing a dam or other wall structures. In their natural environment, rivers function as efficient conduits for transporting water and the supplied sediments composed of both dissolved loads and solid particles. Rivers constantly adapt themselves to a dynamic equilibrium regime through the action of the driving forces and adjustment of their morphological characteristics such as shape and orientation. The equilibrium regime prevails when the transport capacity for water and sediment are balanced with the supply rates. The construction of any barrier such as a dam distributes the natural dynamic status of the river. The kinetic energy of the river flow reduces as the river enters a reservoir. The process leads to reduced transport capacity of sediment in the river, thus causing gradual sedimentation. The sedimentation will take place both in the reservoir and at its upstream in the form of extensive river bed aggradation (sedimentation). The qualitative river response to the dam interception is illustrated using the relationship given by Lane (1955):

$$Q_s D = Q S \quad (1)$$

in which Q = water discharge, S = river slope, Q_s = sediment discharge, and D = the median sediment. Assuming the sediment size and the water discharge are kept constant, the increase in sediment discharge will be accompanied by an increase in the slope according to Equation 2:

$$Q_s^+ D^0 = Q^0 S^+ \quad (2)$$

Equation 2 shows that the river response is aggradation in the upstream channel. This is the backwater effect which results to M1 curve of gradually varied flow. Aggradation can spread to a considerable distance upstream of the dam after a long time and thereby increases the flood stage. The river may adopt a new channel in case of extensive aggradation in its channel. In an analogy to Equation 2, the river bed degradation (erosion) takes place downstream of the dam where the slope decreases due to decreased sediment load, i.e., $Q_s^- D^0 = Q^0 S^-$. The temporal bed profile variations can be estimated from the analytical solution to the Saint-Venant-Exner equations, i.e., Equation 3 (see Graf, 1998):

$$z(x, t) = \Delta h \operatorname{erf}\left(\frac{x}{2\sqrt{Kt}}\right), \quad K \cong \frac{1}{3} \xi q_s \frac{1}{(1-\lambda)S_e} \quad (3)$$

in which z is the bed level, Δh = thickness of the aggradation layer, x = distance, t = time, q_s = sediment load, ξ = coefficient for sediment gradation ≈ 5 (Graf, 1998), and S_e = energy line slope. Equation 3 is only applicable for $x > 3h/S_e$ (h = flow depth) and $Fr < 0.6$. Fr is the Froude number which is the ratio of flow velocity to the square root of acceleration of gravity times flow depth. The values of the error function erf can be obtained from a mathematical table (*Handbook of Mathematical Function* 1964). The length of deposition, L_d of $z/\Delta h = 0.01$ yields from Equation 3 as $L_d \approx 3.65 (Kt)^{0.5}$. Δh can be derived from Equation 3:

$$\Delta h(t) = \frac{\Delta q_s \Delta t}{1.13(1-\lambda)\sqrt{K\Delta t}} \quad (4)$$

in which Δt = time interval and Δq_s = sediment discharge at Δt . To illustrate the use of Equations 3 and 4, consider a river where river slope = 5×10^{-4} , sediment size = 0.32 mm, flow discharge = $1.5 \text{ m}^3/\text{s}$, $q_s = 1.7 \times 10^{-4} \text{ m}^2/\text{s}$, and $\lambda = 0.4$. After 50 h the aggradation thickness will be 0.06 m and its distance 1,500 m (Graf, 1998). The strength of the outlined method lies with its simplicity and applicability to both aggradation and degradation problems.

The right hand side of Equation 1 gives the river stream power when multiplied by ρg , i.e., $P = \rho g QS$, where ρ = density of water and g = acceleration of gravity (Lane et al., 1994). Stream power is an important concept in sediment transport that can be related to the total sediment transport (e.g., Bagnold, 1977) as well as the total sediment concentration (e.g., Yang and Molinas, 1982). The sediment rate G_s (kg/s) becomes proportional to P/D .

Sedimentation process

The sedimentation process in a reservoir is a result of a complex interaction between the various sediment transport processes that prevail in the river and the surface soil erosion as well as the hydrodynamics of the reservoir. To understand the sedimentation process, one must consider the process in three interrelated stages:

(1) the motion of sediment particles, (2) the process of soil erosion in the river basin, and (3) the river channel sediment transport characteristics. All these processes are controlled by a large number of flow parameters, soil or sediment properties, basin properties, and the hydrological variables.

Sediment particle motion

The motion of sediment particles is caused by the combined action of the gravity force working on the sediment particles and the entrainment of sediment particles by flow forces. The latter are the hydrodynamic forces that act upon the particle, producing drag and lift forces. The sediment particles will remain in an equilibrium state as long as the critical particle shear stress is not exceeded. Under increasing flow velocity, the magnitude of the flow forces will exceed the critical shear stress and the particles start to move. The critical shear stress (τ_{cr}) is commonly determined using the Shield (1936) diagram that relates the shear stress to the particle Reynolds number ($u_* D_m/\nu$). The relationship reads:

$$\frac{\tau_{cr}}{g(\rho_s - \rho)} = f\left(\frac{u_* D_m}{\nu}\right) \quad (5)$$

in which g = acceleration of gravity, ρ_s = sediment density, ρ = water density, u_* = shear velocity (hydrodynamic force), and D_m = characteristic sediment diameter. The critical shear stress can also be written in terms of critical shear velocity as ρu_{c*}^2 . Equation 5 is one of the most important relationships used in sediment transport. The left-hand side of the equation assumes a constant value 0.06 for Reynolds numbers greater than 500. Equation 5 only applies to non-cohesive sediment. The complexity of the problem increases with the cohesion of the material that is related to physicochemical forces. The dominant sediment type in most reservoirs ranges from silt to clay with high cohesion. There are no theoretical equations that can describe the motion of cohesive materials because the physical processes are not yet fully understood. The critical shear stress for cohesive particles (τ_{co}) can be estimated from Equation 6 (Lick, 2009):

$$\tau_{co} = \left(1 + \frac{ae^{b\rho_s}}{D_m}\right) \tau_{cr-n} \quad (6)$$

in which $a = 8.5 \times 10^{-16} \text{ m}^2$, $b = 9.07 \text{ cm}^3/\text{g}$, and τ_{cr-n} = critical shear stress of non-cohesive particles N/m^2 . Equation 6 shows that the critical shear stress increases significantly for cohesive particles. The increase is due to the attractive force between the particles. The other important physical parameter is the settling velocity of sediment particles as it is directly related to sedimentation in a reservoir. For a non-cohesive spherical particle, the settling velocity (known also as fall velocity) for Reynolds numbers greater than 1,000 is given by Equation 7 (Chien and Wan, 1999):

$$\omega = 1.72 \sqrt{\frac{\rho_s - \rho}{\rho}} gD \quad (7)$$

The approximate equation for cohesive particles less than 1 mm in diameter reads (Lick, 2009):

$$\omega = 0.268D_m^{1.56} \quad (8)$$

Equation 8 applies to sediment concentrations of 50, 100, and 200 mg/L. The settling velocity of cohesive particles is affected by sediment concentration, salinity, and flocculation (for details see Chien and Wan, 1999). Generally there is a logarithmic relation between settling velocity and sediment concentration. A critical concentration is found at 15 mg/L. The settling velocity increases sharply for values below the critical concentration, but it decreases for values above it. It is also found that the flocculation effect on settling velocity is important when the particle size is less than 0.01 mm. Under this condition the settling velocity increases with the flocculation factor. A fundamental consideration in reservoir sedimentation is the probability and the rate of sediment suspension. The ratio of the settling velocity to the flow shear velocity can be used to decide the probability of sediment suspension. Based on experimental observation, the ratio varies in the range 0.5–5.

One other important aspect that affects the forgoing discussion is the bulk density of sediments that depends on consolidation. An empirical relation is given by Lane and Koelzer (1953) for reservoir applications:

$$\rho_{bT} = \rho_{b1} + B \log T \quad (9)$$

In Equation 8, T = time in years, ρ_{b1} = initial bulk density after 1 year consolidation, and B = consolidation coefficient. Table 1 lists the values of ρ_{b1} and B as functions of reservoir operation.

It should be noted that the sediment motion is statistical in nature due to the fluctuating character of the acting forces.

Soil erosion

Soil erosion starts with the detachment of soil particles by the kinetic energy and momentum of rainfall. The main variables at this stage are rainfall intensity and duration, drop size, and impact velocity. The detached soil particles are subsequently transported downslope by surface runoff (for a summary see Shen, 1971). Surface runoff causes

sheet erosion at its initial stage when the flow velocities are low. Here the main feature is the uniform removal of soil without the development of visible water channels. Rill- and gully-type erosions develop successively as the surface runoff flow increases. Rill erosion is the soil removal from the topsoil layer through many small channels. Rill erosion is hardly visible. Gully erosion is the severe stage where deep channels resembling large ditches are cut through the soil. Substantial amounts of soil are transported by gully erosion. Surface erosion normally occurs when the land slope is at least 2%.

The fundamental causes of both erosion types are the absence of vegetation and unsuccessful soil conservation policies by the agriculture industry. The sediment transport mechanism in both cases is similar to that found in narrow rivers with high slopes. However, the estimation of soil erosion rates requires the application of other methods. The worldwide total sediment yield in the different river basins shows a significant variation from 0.01 t/km² year to several thousand tons. Lahlou (1996) gives illustrative statistics for 73 dam sites in North Africa (Morocco, Algeria, Tunisia). Table 2 summarizes some of the statistics. The sediment yields are very high in comparison with the large rivers in the world (Table 3). The high values are correlated with the extensive reservoir sedimentation problems in these countries.

River processes

In their natural environment, all rivers display a number of classical features, among which are a meandering of the river channel and the formation of different types of river beds (i.e., ripples, dunes, and anti-dunes) and the formation of various types of sand banks and bars. The river channel sediment transport capacity is controlled by the hydraulics of the flow (applied shear stresses), the sediment properties, and the hydrological variables. The available and supplied sediment to the river undergoes different modes of transport during its path along the river. There are two major transport modes: bed load transport and suspended load transport. Bed load transport is the movement of sediment particles in contact with the bed by rolling, sliding, and jumping. Suspended load is transported by the diffusion action of turbulence. The origin of the transported materials is important. The transport that has its origin in a river bed is known as

Reservoir Sedimentation, Table 1 Initial bulk density (kg/m³) and coefficient B for consolidation conditions

Reservoir operation	Sand		Silt		Clay

bed-material transport. Here, the transport mode (either bed load or suspended load) is determined by the bed sediment composition and flow conditions. The external supply of materials (surface erosion) is known as wash load and is not directly related with the river channel flow. Wash loads are normally composed of very fine to coarse silt (4–60 μm) that is transported in suspension. To distinguish between the two material origins is of importance for reservoir sedimentation. Wash load is the main contributor from the river to the reservoir sedimentation. Surface erosion models are needed to estimate the wash load. The annual suspended sediment yield of the major rivers in the world is reported to be 20×10^9 t (Holeman, 1968). Table 3 gives a summary of the annual sediment loads and the sediment yields for ten major rivers in the world (Allen, 1997). It is interesting to note that the sediment yield from the Amazon River basin is relatively low compared to its drainage area and to other major rivers such as the Colorado River and the Ganges River. A major part of the Amazon Basin is covered with dense tropical forest that limits the sediment yield from the basin.

The three other important sources of sediment are riverbank erosion, landslides, and reservoir shoreline erosion. In many cases, riverbank erosion is a natural process that is partly related to the meandering of the river. Figure 2 shows an example of riverbank erosion in the upper river reach of Klarälven, which enters Sweden in the north of the county of Värmland. Riverbank erosion can in some cases be the major contributor to the total sediment load in a river. The U.S. Soil Conservation Service (Serr, 1971) found that the principal sediment sources in the Eel River basin were riverbank erosion (64%), landslides (26%), and sheet and gully erosion (10%). Significant amounts of sediment can enter the river or reservoir by landslide on the valley walls of rivers. The landslide can also act as a natural dam if the eroded material is sufficient to fill the waterway. In such cases upstream flooding can occur. Landslides are related to the topography, geology, and drainage, and flood periods are particularly dangerous in both cases. The landslide handbook (Highland and Bobrowsky, 2008) given by a U.S. Geological Survey is a valuable source of information on the various aspects of landslide and its mitigation.

Reservoir sedimentation processes

The flow in a reservoir is driven by many meteorological parameters such as wind speed and its direction, and the various parameters that are related to the heat energy balance (e.g., temperature, dew point, radiation, and cloud cover). The complex three-dimensional nature of the reservoir flow structure is evident in terms of its thermal stratification, hydrodynamic instabilities, and large numbers of recirculation flow regions with varying size and strengths. There is ample scientific evidence on the influence of the reservoir flow on the characteristics of sediment transport and thus sedimentation in the reservoir (Xing et al., 2002; Scully and Friedrichs, 2003). To understand the reservoir sedimentation, some general reference to flow structure within the reservoir is needed. Figure 3 shows a simplified general view of the ongoing processes in a reservoir along a longitudinal section. The various flow and sediment transport regions are marked at an intermediate sedimentation stage.

A complex mixing process prevails within the reservoir and affects the sediment transport characteristics in the reservoir. Most reservoirs are temperature stratified along the flow depth, having three classical layers of epilimnion, metalimnion, and hypolimnion in the order of decreasing temperature with the flow depth (Martin and McCutcheon, 1999). The top epilimnion layer is warmer and normally well mixed. The stratification in freshwater reservoirs is driven mainly by solar energy, and to a lesser extent, by wind. The river entering the reservoir interacts with the low momentum reservoir in three distinct mixing regions, i.e., riverine, transition, and lacustrine. In the first region the advective forces dominate and keep the water column well mixed. The second region is an intermediate stage between riverine flow and lake flow in which the buoyancy forces (due to density difference) start to increase. In this region the buoyancy forces dominate over the advective forces. The river inflow gives rise to an overflow if its temperature is higher than the ambient temperature and to an underflow if its temperature is lower than the ambient temperature. The temperature differences between the river flow and the ambient reservoir water cause the formation of density currents. Density currents play a fundamental role in reservoir sedimentation. Here,

Reservoir Sedimentation, Figure 2 Riverbank erosion in the upper reach of the river Klaräven, Värmland, Sweden.

Reservoir Sedimentation, Figure 3 A schematic of sedimentation mechanism within a reservoir.

the key parameter is the Froude number based on the density difference:

$$Fr' = \frac{U_r}{\sqrt{g'h'}}, \quad g' = g \frac{\Delta\rho}{\rho} \quad (10)$$

in which U_r = relative velocity between the fluid layers, h' = thickness of density current layer, g = acceleration of gravity, ρ = density of the upper layer, and $\Delta\rho$ = density difference between upper and lower fluids. Another

important parameter for a flow with a density current is the Richardson number defined by

$$Ri = \frac{1}{Fr'^2} \quad (11)$$

The movement of a turbidity current depends on the entrainment of the ambient flow, which is related to the Richardson number by an entrainment coefficient, i.e., $E_u = f(Ri)$. For values of $Ri = 1$ or less, the entrainment is negligible.

The underlying mechanism for reservoir sedimentation is the formation of a special type of density current known as turbidity current. The turbidity current in turn is related to the rate of settling of sediment particles, sediment sorting, and the capacity of the reservoir flow to maintain sediment suspension. Sediment loads are discharged into the reservoir by the river in three parts: (1) bed load, (2) suspended load, and (3) wash load. The type and amount of the loads delivered to the reservoir are controlled by the hydraulics of the river, the geometry of the reservoir, and the section aspect ratio at the entrance to the reservoir (width to depth ratio). Generally, the coarser sediment (sand) does not reach the reservoir because of the aggradation effect of the dam that can travel several kilometers upstream of the entrance to the reservoir. The deposited material is primarily silt and clay. A typical distribution of the sediment types is given in Table 4, which shows the accumulation of sand (bed load) at the entrance of the reservoir. The mid region of the reservoir is dominated by silt, whereas in the outlet area, the clay and silt contents are almost equal. The table also confirms the process of sediment sorting as the deposition layer approaches the dam. The entrance deposition region is commonly known as delta formation. The content of sand can increase by erosion or landslide of the reservoir banks.

The sedimentation process in a reservoir is complex and makes generalization difficult. The details and the structure of deposition patterns are in many cases site dependent. However, the main aspects of the sedimentation process can be considered in three phases that correspond to different regions of the reservoir.

Phase one – This phase begins when the river enters the reservoir. At the entrance to the reservoir, the sediment transport capacity of the river is reduced considerably because of the loss of river flow momentum to the low-momentum reservoir water as well as the dissipation by the river bottom shear stresses. The sediment deposition starts first with larger sediment particles that are transported into the reservoir as bed load (delta formation). The finer sediment particles are suspended by the strong flow mixing in the riverine region. Here, an important issue is the mechanism of delta formation. To clarify this issue, a simplified three-dimensional flow simulation was done for the Ichari Reservoir in India. The longitudinal profile and the flow data were obtained from the Atkinson report (1996). The design storage capacity of the reservoir was 11.55 Mm³ with an annual inflow of 5,300 Mm³. Figure 4

shows the simulation result for a longitudinal cross section of the reservoir. The upper plot shows the path line for the entire reservoir. The lower plot is the enlarged flow paths and velocity vectors at the entrance to the reservoir. The figures clearly indicate a large recirculation flow region as the flow undergoes a three-dimensional boundary layer separation at the reservoir entrance. The reattachment point extends to a distance of about 20% of the total reservoir length. The large recirculation region acts as a sediment trap to cause deposition (delta formation). The formation of large delta regions in the early stages in the Ichari Reservoir in India gives some support to the analysis. The foregoing discussion illustrates the importance of the interaction of the river flow and the reservoir topography at the entrance. However, there might be other mechanisms for the formation of delta regions.

Phase two – In this phase, a part of the suspended sediment is transported to the transition zone at sufficiently high flow velocities. As the particles in the upper flow region start to settle, the sediment concentration begins to decrease from the water surface toward the reservoir bottom. The settling process is faster than a single particle due to the flocculation structure among the cohesive sediment particles. The settling velocity can be 1/100 or even as low as 1/1,000 of a single-particle fall velocity. The sediment concentration increases within the bottom sediment laden flow. A dense underflow layer forms due to the higher density of the mixed sediment. Equation 12 gives the increase in density for the mixed sediment flow:

$$\rho_m = \rho_0 + (\rho_s - \rho_0) C \quad (12)$$

in which ρ_0 = clear water density, ρ_s = sediment density, and C = sediment concentration.

The underflow undergoes a transition from a sediment-laden flow to a turbidity current. During its movement toward the dam, the turbidity flow drags with it a part of the clear water above the interface. To maintain the flow continuity, the other part of the clear water in the upper region must flow backward. The reversal flow often brings any floating material to the surface. The presence of such material can confirm the formation of a turbidity current (Chien and Wan, 1999). Here, the condition for formation of the turbidity current is given by Equation 13, which is based on field and experimental data (Chien and Wan, 1999):

$$\frac{q^2}{\frac{(\rho_s - \rho_0)}{\rho'} g h_0^3} = 0.6 \quad (13)$$

in which h_0 = the water depth at the formation point of the turbidity current, q = flow discharge per unit width at h_0 , and ρ' = density of turbidity flow. From Equation 13, one may conclude that for a constant water level upstream of the dam, with increasing q the turbidity current will move toward dam and an increase in sediment concentration will push back the turbidity current. Thus, high sediment concentration in the riverine region will confine a turbidity

current within a short distance from the reservoir entrance. The movement of the turbidity current toward the dam will continue as long as the longitudinal slope is sufficient to counteract the friction resistance. The propagation speed of the current can be estimated from Equation 14 if the layer thickness (h') is much smaller than the flow depth:

$$U_f' \approx 1.1 \sqrt{\frac{\Delta \rho}{\rho_0} g h'} \quad (14)$$

Equation 14 implies that the speed is independent of the bed slope. However, this is only valid for slopes below 4%. At higher slopes the coefficient 1.1 is a variable (Chien and Wan, 1999). Phase two is characterized by the formation of a fine sand to silt delta region and a mixture of silt and clay in the middle region. There are different possible scenarios on the temporal growth of the delta region. The region can emerge with the bottom layer disposition to form a more or less uniform layer throughout the reservoir. It can also continue to grow with a mechanism similar to the classical riverbed forms such as dunes and anti-dunes. Once an initial deposition forms, the temporal sediment accumulation continues (Figure 3, fine sediment). The deposition grows in size resembling a delta formation. It then propagates downstream as the sediments are removed from the top set and deposited on the forest (Figure 3). The growth and movement of the dune continues until a stage of dynamic equilibrium is

reached. One other scenario is the nonequilibrium stage caused by the transient flow and sediment load boundary conditions at the reservoir inlet.

The third sedimentation phase concerns the turbidity current entering the clear water lacustrine zone. Here, the thickness of the turbidity current increases further and a large clay deposition region forms behind the dam. A dynamic equilibrium stage can be reached if the turbidity layer slope decreases sufficiently to counteract the driving force of the turbidity current. However, to ensure such a condition, there must be an overall dynamic equilibrium prevailing in the river, implying that a natural armor layer (erosion protection) is developed along the riverbed, the river banks are stable, and the total sediment loads have decreased. The situation is rather unique and is more typical of mature rivers with limited surface soil erosion. An example is the reservoirs in Sweden that, even after 45 years, show little signs of any sedimentation of concern.

The foregoing sedimentation process is one possible scenario among many others. The main aspects are strong three-dimensional and transient characters of the process and the existence of different sedimentation patterns that normally appear along the lateral direction for the same reservoir. Three patterns of uniform, tapering, and wedge sedimentations are possible (Morris and Fan, 1997). The variations in the sedimentation patterns are partly caused by the dynamic boundary conditions. Another important

aspect is the sedimentation time scale. The sedimentation is a slow process in comparison with the flow time scale that can either halt after reaching some kind of dynamic equilibrium or may continue indefinitely until the entire reservoir is filled with sediment. The reported time spans are from 25 to 50 years.

Figure 5 shows an example of reservoir sedimentation in the Dez Reservoir. The dam was constructed in 1963 and is located in the Province of Khuzestan in southern Iran. It is a doubled-curvature concentric arch dam with a height of 203 m and a designed storage capacity of $3,315 \text{ Mm}^3$. The figure shows the various longitudinal sedimentation profiles for the period 1963–2003. The sedimentation rate was $20 \text{ Mm}^3/\text{year}$. The interesting feature is the formation of a uniform sedimentation layer in the initial 9-year period. The delta formation appears

from 1972 onward. The Dez Reservoir case clearly demonstrates the diversity and complexity of the sedimentation patterns in a reservoir. Furthermore, uniform deposits do not appear to be only a feature of narrow reservoir with small loads of fine sand as indicated by Morris and Fan (1997).

An example of extreme reservoir sedimentation is shown in Figure 6. It shows a photograph of the Gap weir, Werris Creek, NSW (Australia), on 13 June 1997 viewed from the left bank. The reservoir was fully silted in less than 25 years. Two examples of rapid sedimentation (12 years) are given by Atkinson (1996) for two reservoirs in India. The Welbedacht Reservoir in South Africa, completed in 1973 with a 152.2 million cubic meters storage capacity, lost most of its storage capacity (66%) within the first 13 years of its existence (Rooseboom, 1992).

Estimating sedimentation rate

The initial estimate of reservoir sedimentation rate can be obtained from a number of empirical design equations, and charts. Most of these equations are based on field data collected primarily in reservoirs in China and the USA. Their use in other cases requires some kind of calibration and validation. Two widely used methods are the Churchill method and Brune curve (see Morris and Fan, 1997). Churchill (1948) related the sediment release efficiency to the sedimentation index. The latter was defined as the ratio of the retention period to the mean flow velocity through the reservoir. The application of the method requires the storage volume, annual inflow, and reservoir length. A similar approach was suggested by Brune (1953) who related the capacity/inflow ratio (C/I) to the trap efficiency observed in reservoirs in the southeastern USA. Here, the trap efficiency (η) of a reservoir was defined as the ratio of storage capacity to the inflow. η is a function of age and shape of the reservoir, outlet type and its operation, and sediment characteristics. Various design curves were given to compute η as a function of C/I (Brune, 1953, Fig. 6).

Alternatively, the fraction of material deposited over the total settling basin length in percentage can be estimated from Equation 15 (Shen, 1971):

$$P = 1 - \frac{1}{e^{\frac{1.055l\omega_s}{Vd}}} \quad (15)$$

in which l = settling basin length in ft, ω_s = sediment fall velocity in ft/s, V = average flow velocity in ft/s, and d = water depth in ft. The equation yields the quantities of sediment deposited with given particle size. The total volume of sediment deposited in acre-feet is the sum of these quantities. The trap efficiency is calculated by dividing sediment inflow by the total sediment deposited.

The rate of loss of storage capacity (α in percent) for 25 reservoirs in China was found to be related to the annual rate of erosion (G), reservoir storage capacity (V), and drainage area (F), as estimated by Equation 16:

$$\alpha = 0.0002G^{0.95} \left(\frac{V}{F} \right)^{-0.8} \quad (16)$$

in which the units are G in t/km^2 , F in m^2 , and V in m^3 . Equation 16 applies to small and medium-size reservoirs (Xiaoqing, 2003). The same reference lists a set of empirical equations for estimating the depletion of the reservoir. Equation 17 gives the basic form:

$$V_t = V_0 \left(1 - \frac{W_s}{V_0} \right)^t \quad (17)$$

in which V_t = storage capacity at t years of reservoir operation, V_0 = initial storage, and W_s = annual sediment load (m^3).

The next step is to compute the reservoir capacity. A common method is the average-end-area method (Shen,

1971), which is based on taking the average of several areas of successive horizontal planes and multiplying the result by the contour intervals. The total reservoir volume (capacity) is then calculated by application of Simpson's rule.

A practical model called HYDROMED was used to compute the risk or the probability of reservoir sedimentation referred as to probability of failure in semiarid Mediterranean catchments (Ragab et al., 2001). The probability of failure was found to be low for the El-Gouazine catchment in Tunisia.

In recent years, a number of new methods have been used to compute the reservoir capacity and the sedimentation rate such as Cs-137 and GIS. Walling and He (2002) found the Cs-137 method useful for validation of distributed soil erosion and sediment delivery models. Durbude and Purandara (2005) give a successful application of remote sensing and GIS techniques to the Langanamakki Reservoir in India. The application of the Cs-137 method to reservoir sedimentation is growing. The main principal is to use Cs-137 to calibrate and validate soil erosion and sediment load models. McIntyre (1993) determined reservoir sedimentation from sediment cores with Cs-137 dating techniques. The dating techniques were correlated with reservoir sedimentation by relating sediment deposition to potential sediment production. The latter was determined by the Universal Soil Loss Equation (USLE).

Modeling of sedimentation

A two-step approach must be used to model the reservoir sedimentation successfully. The approach involves modeling the rate of sediment transport both at a larger river basin scale, and at the river channel scale. The basin model yields the sediment load or the erosion rate initiated by surface runoff and the kinetic energy of raindrops (precipitation). The river model quantifies the morphological characteristics of the river subject to sediment yield entering from the river basin. Presently, there are many different types of numerical models in both categories of basin and river modeling. However, there is an important fundamental difference between these categories. River basin models have a pronounced semiempirical nature that is mainly based on the concept of the Universal Soil Loss Equation. Expressed differently, the actual erosion processes are not modeled, whereas the river channel models are mainly theoretically based in their use of the fundamental equations of motion and mass conservation. The general features of each modeling approach are given. There are a large number of noncommercial and commercial models available. Here, the models were selected based on their extent of application, physical principals, and the ease and availability to the user. Commercial or license-based models are excluded from this discussion.

River basin erosion models

In their simplest form, these models relate the rate of soil erosion to rainfall characteristics. The rates of erosion

are separated into rainfall and runoff-induced (Shen, 1971). The transport by rainfall and surface runoff are given by Equations 18 and 19, respectively.

$$T_R = S_{TR}SI \quad (18)$$

$$T_F = S_{TF}q^{5/3}S^{2/3} \quad (19)$$

in which S_{TR} = soil transport coefficient, S = slope steepness, I = rainfall intensity, S_{TF} = soil transport coefficient by runoff, and q = runoff flow rate. The numerical values for the coefficients were given for soils found in the USA (Shen, 1971). The application of equations is straightforward; however, the site-specific coefficients must be estimated correctly.

A more general method is to use the USLE that incorporates many variables. The erosion yield from a river basin depends on a large number of variables, among which are the mechanical and dynamic properties of the soil; the type, size, and slope of the basin; and hydrological and metrological factors. These models have a general universal form given by Equation 20 for determining the mean annual soil loss A (t/ha/m-t):

$$A = RK (LS) CP \quad (20)$$

in which the soil erodibility is expressed by K (t/ha/m-t), R (t/ha/m-t) is related to rainfall force, LS is the hill length-slope factor (i.e., gravity force), and C and P are soil cover factors.

A general feature of USLE based models is their ability for long-term predictions of soil erosion. Jebari and Olsson (2009) give an example of the application of the USLE model in predicting soil erosion in semiarid regions of Tunisia. The two most commonly used models are Soil Water Assessment Tool (SWAT) and the Water Erosion Prediction Project (WEPP) model. The two models are process-based, distributed parameter, continuous simulation, and erosion prediction models. The sediment yield (Q_s metric tons) in SWAT is computed from Equation 2:

$$Q_s = 11.8(Q_{\text{surf}} q_{\text{peak}} A_{\text{hru}})^{0.56} K LS CP C_{\text{frg}} \quad (21)$$

in which Q_{surf} is the surface runoff volume (mm/ha), q_{peak} is the peak runoff (m^3/s), A_{hru} is the area of HRU (ha), and C_{frg} is the coarse fragment factor. The SWAT model is widely applied to different regions of the world. An example is the application of the model to the Lake Tana Basin, Ethiopia (see Setegn et al., 2009). It should be noted that the models only account for long-term rill erosion and deposition processes; gully erosion is not included. Empirical equations are available for estimating the rate of gully and cave erosion (e.g., Xiaoqing, 2003). The WEPP model simulates three main physical processes of detachment, transport, and deposition. Surface erosion (inter-rill and rill) and channel erosion are summated as a function of shear stresses induced by flow. In an analogy with SWAT, WEPP does not model gully erosion. An interesting application of the WEPP model for slope analysis is given by Acharya and Cochrane (2009).

Another useful model is the WaTEM/SEDEM model that has its focus on the spatial variation of the related variables. WaTEM/SEDEM focuses on the prediction of water erosion and sediment delivery to rivers. The water erosion component is based on the Revised Universal Soil loss equation (RUSLE) for calculating mean annual soil loss values. The model can also simulate the impact of various scenarios of an integrated catchment management that includes soil conservation methods.

It should be noted that the applications of each of these models need extensive calibration and validation. The research results indicate that Cs-137 measurements can provide a good base for validation of the distributed soil erosion models such as WEPP (Walling and He, 2002).

The interested reader is referred to Bathurst (2002), where one finds some additional models and a comparison table. A complete list of various soil erosion models and download links are available at: http://soilerosion.net/doc/models_menu.html.

River channel transport models

General aspects

River channel models use different numerical methods to solve the conservation equations of mass and momentum. They range from simple, one-dimensional to complex, three-dimensional models. The basic one-dimensional equations for a river reach with area A , and an averaged velocity v read:

$$\frac{\partial(Av)}{\partial t} = -v \frac{\partial A}{\partial x} - A \frac{\partial v}{\partial x} \quad (22)$$

$$\frac{\partial(Av)}{\partial t} + \frac{\partial(Av^2)}{\partial x} = -Ag \frac{\partial h}{\partial x} + gA(S_0 - S_f) \quad (23)$$

in which h is the mean flow depth, S_0 is the channel bed slope, S_f is the friction slope which for a uniform flow could be obtained from the Darcy–Weisbach equation (f = friction parameter, g = acceleration of gravity, and R = hydraulic radius). The friction parameter is:

$$S_f = \frac{v^2 f}{8gR} \quad (24)$$

The sediment continuity equation is then used to compute the rate of change of the river bed:

$$\frac{\partial z}{\partial t} + \frac{1}{1 - \lambda} \frac{\partial q_s}{\partial x} = 0 \quad (25)$$

in which q_s = the total sediment discharge and λ = porosity. Modeling the sediment discharge is the underlying difficulty in applying Equation 25. Presently, there are no theoretical equations available for estimating the sediment load. The sediment discharge (bed or suspended loads) is estimated using semiempirical equations that are based on experimental data obtained from flume studies. There are a large number of equations available that have been applied with varying degrees of success (see Graf, 1971;

Chien and Wan, 1999; van Rijn, 1990). The latter is a comprehensive reversion of principals of sediment transport in rivers, estuaries, and coastal regions. Some popular equations with extensive applications are Engelund-Hansen (1967), Meyer-Peter and Muller (1948), Ackers and While (1973), and Van Rijn (1987). The bed load equations are normally based on the critical shear stress concept. They assume a general form given by Equation 26:

$$q_{s,b} = m(\tau - \tau_c)^n \quad (26)$$

in which m and n depend on the sediment properties and τ is the shear stress. Among available equations, the Van Rijn (1984) equation has shown promising results. It reads:

$$q_{s,b} = 0.053 \frac{T^{2.1}}{D_*^{0.3}} D \left(gD \left(\frac{\rho_s}{\rho} \right) - 1 \right)^{0.5}, \quad (27)$$

$$T = \frac{u_*^2 - u_{*c}^2}{u_{*c}^2}, \quad D_* = D_{50} \left(\frac{\rho_s - \rho}{\rho} \frac{g}{v^2} \right)^{1/3}$$

in which T = transport parameter, D_* = particle parameter, u_* = shear velocity obtained from the velocity profile or the water surface slope, D_{50} = particle diameter not exceeding by 50%, D is usually taken as D_{50} , and v = kinematics viscosity. Numerical methods are needed to solve Equations 22–25. The most common approach is based on a control-volume concept using a finite difference scheme. The domain is divided into a number of rectangular or curvilinear cells. The control volume method is then applied to each cell to ensure the conservation of mass and momentum within each cell (see Patankar, 1980). Some sediment models also account for sediment gradation and sorting as well as armor effects.

Modeling erosion in cohesive soils

The treatment of soil erosion in cohesive soils requires a different approach from that used for equations similar to Equation 27. It has been shown that for the range of bulk properties (ρ_b), the rate of erosion (E) in cohesive soils is well approximated with Equation 28 (Lick, 2009):

$$E = A \tau^m \rho_b^n \quad (28)$$

in which A , m , and n are constants. This equation is similar to Equation 26 that relates the rate of erosion to the excess shear stress. Good approximations for the coefficients are $n = 2.23$, $m = -5.6$, and A is assumed to have a value in the range $2 \times 10^6 - 4 \times 10^5$. The bulk density can be computed from Equation 9 in the case of reservoirs. Equation 28 can be rewritten as Equation 29 by defining the critical shear stress as the shear stress at which erosion rate is 10^{-4} cm/s:

$$E = 10^{-4} \left(\frac{\tau}{\tau_{co}} \right)^n \quad (29)$$

Equation 6 can be used to estimate the value of critical shear stress. In most numerical models that account for

cohesive sediment, Equations 28 and 29 are implemented. However, the use of these equations needs verification of the coefficients. Normally, the rate of erosion is determined in special types of hydraulic flumes such as SEDFLUME or rotating cylinder apparatus.

The application of sediment discharge equations requires the values of many hydraulic and sediment parameters. These equations have a limited scope and applicability to field situations due to their experimental character. To obtain a first estimate of the suspended load, regime-type equations can also be used. These equations have been widely used for many rivers in India and Pakistan in the design of stable channels. They relate the suspended sediment discharge (Q_s) to flow discharge (Q) by a power type equation, i.e., $Q_s = AQ^B$. The value of the exponent B is roughly 2 for a number of major rivers in Japan, Pakistan, Romania, and the USA (see Dargahi, 1985). For the Swedish rivers, the coefficients are $A = 2.4$ and $B = 1.6$. The regime equation gives only an estimate of the suspended load, which is still useful considering the fact that the suspended load is often a major portion of the total load in many rivers that enter a reservoir. The examination of the field data and experimental data shows that the bed load transport is on average about 20% of the total load. However, the ratio can show a great variation among different rivers. For example, Petkovic et al. (1999) indicated that total annual bed load transport in Serbia is about 10% of the suspended load. Emmett and Thomas (1978) give interesting field data on both bed and suspended loads in the Snake River near Lewiston, Idaho.

Available models

The available models can be classified into three groups: 1-D (including kinematic wave models), 2-D, and 3-D models. Table 5 gives a summary of the most common models.

The models in Table 5 are easily downloadable. Otherwise, the actual number of models exceeds the list (see Przedwojski et al., 1995). One-dimensional models give reasonable predictions of the morphological changes. They are relatively easy to use and the data requirements are not as extensive as for 2-D or 3-D models. The simplest form of 1-D models are kinematic wave models that are based on simplifications of Equations 22–25. They are especially suitable for studying the long-term response of a river to changes in the sediment load. They are also effective tools for initial investigation of the long-term sedimentation trends in reservoirs. In the previous section, the bases of the models, application areas, and the analytical solutions were presented (Equations 3 and 4). In contrast to the kinematic models, fully 1-D models offer a greater flexibility as the basic equations are fully model-solved for both steady and unsteady flow conditions. The other advantage is the possibility of modeling river networks. However, numerical methods must be used to solve the flow and sediment transport equations. Two popular models are HEC-RAS (HEC-6)

Reservoir Sedimentation, Table 5 Summary of downloadable flow and sediment transport models

Model name	Dimension	Application
DELTA	1-D simplified	Flow and sediment transport. Applicable to reservoir sedimentation. Valid for Froude numbers <0.6. The Fortran source code available (Graf, 1998)
HEC-RAS	1-D	Flow in river network flow, sediment transport, and water quality. Applicable to reservoir sedimentation. Hydraulic sorting included. Long-term predictions possible. Cohesive soil erosion is not modeled
HEC-6	1-D	Sediment transport model to calculate water surfaces and sediment bed surface profiles
CCHE1D	1-D	GIS based river network model for flow and sediment transport. Applicable to reservoir sedimentation. Cohesive erosion is not modeled
CCHE2D	2-D-depth averaged	River flow and sediment transport for non-cohesive graded sediment. Cohesive erosion not modeled
ECOMSED	3-D	General hydrodynamic, sediment transport, and water quality models. Applicable to rivers and reservoirs. Surface erosion models are not included. A large number of applications are available. These models can be used for long-term predictions Cohesive erosion is modeled
EFDC	3-D	
GEMSS	3-D-GIS based	
FVCOM	3-D	

and CCHE1D that are well documented with many application areas. A successful application of HEC-RAS is given by Emmett and Thomas (1978). They applied HEC-6 to Lower Granite Reservoir at Lewiston, Idaho to compute the bed profiles. The model results were used to evaluate the dredging needs associated with Lower Granite Reservoir.

The 2-D models are mostly depth-averaged models that bring the physics closer to 3-D models. In depth-averaged models, the vertical acceleration is assumed to be constant. Among various models, CCHE2D is a good model with documented applications (e.g., Dargahi, 2008). The disadvantage of this model is its limitation to non-cohesive sediment.

The final group of models is that of 3-D models as listed in Table 5. These models are comprehensive hydrodynamic, sediment transport, and water quality models. The listed models share many common features. To get some insight into these models, an outline of GEMSS is

given. GEMSS (Generalized Environmental Modeling System for Surfacewaters) is a state-of-the-art, 3-D, time-dependent hydrodynamic, transport, and water quality model that is embedded in GIS. The hydrodynamic and transport relationships are developed from the horizontal momentum balance, continuity, constituent transport, and the equation of state. The model accounts for the atmospheric forcing conditions (cloud cover, humidity, pressure, radiation, rainfall, solar energy, and wind speed and direction). It is applicable to both non-cohesive and cohesive sediments.

The foregoing 3-D models are particularly valuable tools for studying the flow and sediment transport characteristics in reservoirs. Their usefulness lies with their ability to account for the atmospheric forcing conditions, which are of significant importance as the primary driving force in reservoirs and other large open water bodies. There is a gap in the present knowledge about interaction of the stratified reservoir flow with the sediment loads discharged into the reservoirs. By using these state-of-art models, the subject of the reservoir sedimentation can be advanced to new horizons. However, the undertaking of the task would require extensive data for the boundary conditions and the reservoir itself. The data are needed both for the model setup and for the calibration/validation process. The possibility of success is good, given the extensive literature and published field data on this topic.

Mitigation methods

The mitigation of the reservoir sedimentation requires a system approach that compromises the river basin, the river channel, and the reservoir. The lack of an integrated design is of one the main reasons for many cases of extensive reservoir sedimentations around the world. No isolated measure can serve as a sustainable method. The mitigation should also be viewed in a larger perspective by understanding the socioeconomic aspects. The topic is beyond the scope of the present writing, but its importance is nevertheless emphasized. Preserving precious topsoil from erosion is one of the greatest environmental challenges of the twenty-first century. This preservation should be an inseparable part of a sustainable mitigation plan. A good teaching example is the successful mitigation plan of Coon Creek Basin in Wisconsin (Trimble and Lund, 1982).

Mitigation methods concern both the sedimentation sources and the actual reservoir sedimentation. The methods are applicable both prior to the construction of a dam and during its design lifetime. The mitigation methods can be classified into two groups: one concerns the river basin and the other deals with the sedimentation problem in the reservoir. Expressed differently, there is a need to address feasibility of mitigation methods for controlling the source of sediment supply and its consequences for a reservoir. It should be emphasized that there are no universal methods or solutions. The choice, feasibility, and success of a method are always dictated by

the local conditions. However, the execution of the task can greatly benefit from the enormous available resources of field applications and scientific advancements (e.g., Bruk, 1985; Palmieri et al., 2003; Xiaoqing, 2003; DFID, 2004; Althaus and Cesare, 2006; Lee et al., 2009). A schematic of the main methods is in Figure 7.

Soil conservation measures

The underlying concepts for the enforcement of various soil conservation measures include the reduction of the erosive power of the surface runoff flow and the maintenance of a good quality soil cover that enhances infiltration. These objectives could be achieved by changes in land management and/or the use of engineering structures. Sanders (2004) gives a comprehensive look into the various aspects of soil conservation. An indispensable source of information on soil conservation measures is the US National Conservation Practice Standards (2010) that is regularly published and updated by the Natural Resources Conservation Services (NRCS). It provides much valuable information on the use of a vast number of different conservation methods, among which are: terrace (NRCS, code 612), contour farming (NRCS, code 330), conservation cover (NRCS, code 327), conservation crop rotation (NRCS, code 328), and tree/shrub establishment (NRCS, code 612). Terracing the land is an effective method of reducing soil erosion and has been used around the world for centuries. An example of terracing is found in the famous Banaue rice terraces in the Philippines that are estimated to be 2,000 years old. There are many examples of successful implementation of terraces in China, Ethiopia, India, and Yemen. Rajan (1982) reports a significant reduction in the rate of sedimentation for Tungabhadra Reservoirs in India. A combined approach

of contour bunding, sediment trapping, and divergence of sediment laden flow was used. In a short 6-year period (1972–1978), the sedimentation rate was decreased from $96 \times 10^6 \text{ m}^3$ to $16 \times 10^6 \text{ m}^3$ per unit area. For the same period, the rate of reduction for Guanting Reservoir in China was 90% of the total amount of deposition (Bruk, 1985; Xiaoqing, 2003).

Flushing of the reservoir

Reservoir distillation by means of flushing is widely practiced in many parts of the world. The basic principal is to cause erosion in the deposited material by opening the bottom outlets of the dam. The effectiveness of the operation depends on many parameters, among which are the hydraulic conditions; the type, extent, and properties of the deposition; the reservoir water level; and the operation of the bottom outlets. Two types of flushing are possible: pressurized flushing and free-surface flushing (Morris and Fan, 1997). Pressurized flushing requires a moderate drawdown during which the pressurized hydraulic conditions prevail in the bottom outlets. In free-surface flushing, a free-surface flow condition is created in the bottom outlets when the water level reaches the level of the bottom outlets. The erosion characteristics are mainly localized for the pressurized case (e.g., Lai and Shen, 1996; Shen, 1999; Emamgholizadeh et al., 2005; Meshkati et al., 2009). The flow-induced shear stresses are only sufficient to cause a local flushing cone. The deeper the reservoir, the shorter the erosion distance upstream of the outlet. In reservoirs with low-level outlets for a flow discharge of 150 m/s, the erosion distance varies in the range 20–100 m, for reservoirs depths of 5 and 50 m, respectively (Atkinson, 1996). Figure 8 shows a photo of the pressurized flushing through the irrigation outlets at Dez dam. On June

Reservoir Sedimentation, Figure 7 A schematic of different reservoir sedimentation mitigation methods.

Reservoir Sedimentation, Figure 8 Pressurized flushing of the bottom outlets at the Dez Reservoir. (Courtesy of Dr. Emamgholizadeh.)

17, 2003, pressurized flushing was done that lasted for 4 h. The purpose was to remove the accumulated sediment ($D_{50} = 0.002$ mm) in the vicinity of the dam that was 30 m above the centerline of the irrigation outlets. A flushing cone with a diameter of about 400 m was created within a 100-m distance of the dam. The total volume of flushed sediment was 3 Mm^3 (Emamgholizadeh et al., 2005).

Free-surface flushing is recognized as an effective method in reducing reservoir sedimentation (e.g., Atkinson, 1996; Morris and Fan, 1997; White, 2000). It relies on the drawdown of the reservoir water level to the level of the bottom outlets and is more effective during flooding season. The sediment transport process is typically characterized by the rapid evolution of an erosion channel that extends upstream in the flood plain and deepens continuously. The process is commonly referred to as “retrogressive erosion.” Two main issues must be considered in using this method. One is its effectiveness and the other is the modeling of the flushing process in terms of the sediment load. The effectiveness of the free-surface flushing depends on the storage capacity and the shape of the reservoir. The method is effective in small reservoirs where the storage capacity is less than 30% of the mean annual flow and reservoirs in steep sided valleys (White and Bettess, 1984). Free-surface flushing is also restricted by the downstream impact of the enormous loads of flushed sediments. Atkinson (1996) lists six cases of successful reservoir flushing in India, Austria, China, Switzerland, and Venezuela. The recovery in storage capacity varied from 20% to nearly 100% of the original capacity. The flushing times varied from hours to 1.5 months. Cases of unsuccessful flushing concerned large reservoirs ($>14 \text{ M m}^3$) and errors in the design of

outlet structures. Two important criteria were developed by Atkinson (1996) for the feasibility assessment of flushing:

1. A sediment balance between the sediment mass flux and the sediment deposition during the flushing operation
2. A capacity criterion that assesses the long-term storage capacity

Numerical examples in using the two criteria were also provided.

Several methods are available for modeling the sediment transport characteristics during the flushing process. They range from empirical equations (Shen et al., 1993) to the application of 1-D morphological models (Lai and Shen, 1996) to more complex 2-D (Shen, 1999) and 3-D models (e.g., Khosronejad et al., 2008). However, the application of the latter models is limited. There are two major limitations to the application of these models, one is the proposed equations and models are often based on small-scale physical model studies and need many parameters that are site specific, and the second important restriction is the use of non-cohesive soil properties, which can be a serious concern. Cohesive soils are more erosion resistant than non-cohesive soils. The critical shear stress for the initiation of sediment motion can be 10 times higher than for non-cohesive sediment. The deposition can also have a consolidated character that further increases the resistance to erosion.

To estimate the sediment discharge for the free-surface case under uniform flow conditions, Equation 30 is proposed (Lai and Shen, 1996):

$$Q_{os} = E \frac{Q_o^{1.6} S^{1.2}}{B^{0.6}} \quad (30)$$

in which Q_o is the outlet discharge, m is the Manning coefficient, S = bed slope, B = flushing channel width, and E = coefficient of erodibility. The equation was partly based on field data collect in China. Values of 180, 200, and 650 were proposed for E . The lower the E value, the higher the erosion resistance. To determine the equilibrium channel width, Equation 31 is proposed:

$$B_e = 10.91 Q_d^{0.5} \quad (31)$$

in which Q_d = dominate discharge. The interesting feature of Equations 30 and 31 is their similarity to the regime (Lacey) equations for stable channel design. Regime equations were original developed by Lane for a river in India. The modified equation by Blench for the channel width is

$$B = k Q^{0.5} \quad (32)$$

$$K = \left(\frac{F_b}{F_s} \right)^{0.5}, \quad F_b = 1.9 d^{0.5} \quad (33)$$

in which d = sediment size in mm and F_s depends on cohesion properties of the sediment. F_s has assumed values of 0.1, 0.2, and 0.3 for slightly, medium, and highly cohesive sediments, respectively. The comparison of Equations 31 and Equation 32 shows the regime characteristics of Equation 31. It also suggests the importance of including the cohesion effect for estimating the equilibrium width of the flushed channel.

River bypass measures

An effective method to reduce the sediment inflow to the reservoir is the construction of bypass channels. The basic principal is to divert the sediment-laden flow through a channel or a tunnel. The method is especially effective during flood periods that carry high sediment concentrations. Compared to flushing, the method is more sustainable, but it requires large volumes of water during diversion. Bypass channels have been applied to many reservoirs in the world (Batuca and Jordaan, 2000). They are more effective in combination with low dams. An example is the Hushan Reservoir built in north China in 1969. By 1976, 54% of the reservoir capacity was lost due to sedimentation. The sedimentation rate decreased to 1/13 of the annual average following the construction of a small dam for flood detention at the entrance of the reservoir and a diversion channel. The channel diverted the sediment downstream of the dam (Bruk, 1985). Two other interesting successful cases are two small reservoirs in Switzerland. A 305-m-long diversion gallery was built at the small reservoir called Amsteg Reservoir. No sediment deposition was measured after 3 years of operation (Reed, 1931). The small Palagnedra Reservoir in the southern part of the country was subject to extreme sedimentation problems after its completion in 1953. No significant sedimentation was recorded following the construction of a diversion channel. Further successful applications are listed by Batuca and Jordaan (2000).

Mechanical removal

Dredging is a common method used to remove deposited sediments in small to medium-size reservoirs. The handbook on dredging gives a comprehensive review of the subject (Herbich, 1992). The method has many other application areas, among which are the maintenance of navigation channels, shoreline dredging, and creation of artificial islands. The type of the dredging equipment depends on the application area. Here, three main types of equipment could be used, i.e., dipper, bucket, and ladder. However, hydraulic dredging could be more advantageous as the unit is self-contained. It manages both the digging and the disposal of the material by either pumping or storing it in hoppers (Herbich, 1992). The method has two disadvantages. One is the high cost (about \$2–\$5/m³) and the other is the possible release of contaminated sediment. The dredging equipment creates a local flow field that is characterized by high levels of turbulence intensities and secondary

flow regions. Consequently, the contaminated sediment may cover the entire water column. In such cases, special equipment is needed (Herbich, 1992). RRESCON (Palmieri et al., 2003) gives a detailed analysis of both economical and technical aspects of sediment removal. The highest amount of sediment removed by dredging is reported as 11 million tons (same source). The amount might be the upper limit being manageable both economically and technically. Trucking is an alternative method that involves dry excavation and requires lowering the reservoir water level during dry seasons.

Siphon dredging

The method relies on using the hydraulic head available at dams as an energy source for dredging. Reh binder (1994) investigated the physics of the siphon dredging. The submersion depth appears to be the most important parameter. The theory indicates that right below the mouthpiece of the siphon, the sediment will be subject to compression and not to any lift. The method has been applied to small reservoirs around the world. In China, siphon dredging has been used for small reservoirs in semiarid regions. In these cases, the discharge range was 0.2–1.2 m³/s using pipes in the range 0.3 m–0.6 m. The maximum removed sediment concentrations were in the range 500–1,200 kg/m³ (Xiaoqing, 2003).

Sluicing of turbidity currents

Sluicing or venting of the turbidity currents through a low-level bottom outlet is a possible approach for reservoir distillation (Morris and Fan, 1997; Batuca and Jordaan, 2000). The success of the method depends on the proper location of the outlets and their operation. They should be synchronized with the turbidity currents and their discharge characteristics. The two foregoing issues limit the application of the method.

Normally, the method is most effective in narrow reservoirs. The release efficiency for a turbidity current is normally expressed as a function of reservoir length and the discharge ratio. The former is defined as the ratio of inflowing to outflowing turbidity current, and the latter is the ratio of flow rate of inflow to the turbidity release. The relationship between the two ratios was developed for Guanting Reservoirs and is given in a figure (Morris and Fan, 1997). The shorter the reservoir length, the higher the venting efficiency. Bruk (1985) gives many examples of turbidity currents and their venting in different reservoirs around the world. Sloff (1997) discusses the application of a two-layer computational model for computing the type of turbidity currents common in reservoirs. The model can be used to support the design and operation of the method. Two interesting cases are discussed by Muller and Cesare, 2009 for reservoirs Gigerwls and Mapragg in Switzerland. Large sediment loads were transported by turbidity currents into the Mapragg Reservoir during flood seasons. The opening of the bottom outlet caused the turbidity current to be

vented. The solid transport through the outlet was estimated as 6,000 t. It was also pointed out that if venting started at 2 g/L, the cost would equal to the cost of mechanical removal. The operation of the bottom outlet is automated to a threshold sediment concentration value. The outlet was closed when the sediment concentration fell below 2 L/g. The concept of automated operation is a good model for other reservoir sites where venting is an option. In recent years, the possibility of causing erosion in the fine bed sediment has been addressed in some research papers (e.g., Sequeiros et al., 2009). The basic idea is to erode the fine sediment by wall jets and the subsequent transport by a turbidity current. Experiments and a numerical model confirmed the applicability of the method; however, the results concerned only non-cohesive sediment.

Other measures

Riverbank and shoreline erosions could serve as significant sources of sediment to a reservoir. In those rivers that can maintain a natural dynamic balance state, riverbank erosion does not pose a serious threat, as the additional sediment load is often distributed within the river system. In other cases where anthropogenic activities dominate the riverbank, erosion is accelerated (e.g., Figure 2). In the section "River processes," it was noted that 64% of the total sediment load in California's Eel River originated from bank erosion. The extent of the problem will significantly increase if riverbank erosion assumes the character of a landslide. Landslides are known to deliver excessively large quantities of sediment to rivers. Similar problems could be encountered when shoreline erosion in reservoirs is an ongoing process. In these cases, the wind and the water level variations are the main causes of erosion.

In summary, reservoir sedimentation rate can be decreased by mitigating riverbank erosion and shoreline problems. In recent years, significant progress has been made in river training techniques (Przedwojski et al., 1995; Biedenharn et al., 1997; Beck, 2006). The popular techniques are revetments and groynes (Figure 7). However, the application of vanes holds promising results. The main methods used for counteracting landslides are change of slope, drainage, counter weight filling, anchors/walls, and chemical methods. Good coverage of the topic is found in many articles and handbooks (Cruden and Varnes, 1996; Highland and Bobrowsky, 2008; Acharya and Cochrane, 2009).

Environmental consequences

The future availability and development of sustainable and renewable energy sources hold the main key for the continuous progress and prosperity of human societies. Recent scientific developments confirm a trend of shifting from more fossil fuel-based energy sources to more environmentally acceptable sources such as wind energy and solar energy. Among the different sources of energy, traditional hydroelectric energy remains as an important

renewable source. The importance of hydropower lies in its potential for regulating and optimizing energy delivery as well as adaptation to the growing environmental demands. Despite all the benefits, the construction of a dam puts serious restraints on the environment. Here, only a general outline is given, as the details of the problem are beyond the scope of the present writing. The problems can be recognized in two different areas. One is the blockage effects on the intake structures as well as the risk for severe erosion of turbine components, including the blades. Sedimentation also results in a loss of revenues and availability of water for drinking and irrigation. The environmental problems occur both within and outside the reservoir. In the former case, the water quality may be affected due to nutrients and oxygen deficiency. A serious hazard will occur if the bottom sediment is contaminated with heavy metals and other harmful chemical substances. The oxygen deficiency is a consequence of chemical and bacterial reactions that consume oxygen. These in turn will threaten the fish habit. There is also a serious risk that the contaminated sediments could be released into the water body during reservoir flushing or similar operations. On a large scale, the imposed change on the river will adversely modify its morphological activities. Upstream of the dam, river bed aggradation increases flood risk and riverbank instability problems. The flood risk will increase significantly if the storage capacity of the reservoir is compromised. Downstream of the dam, serious morphological problems can occur such as extensive riverbed erosion, river bank failures, and modification of the delta regions and coastal lines. Some of these topics are adequately covered in many handbooks and articles (Shen, 1971; Bruk, 1985; Lahlou, 1996; Morris and Fan, 1998, and FISC, 2006). Figure 9 summarizes the foregoing facts.

Concluding remarks

Reservoir sedimentation is a process that involves the gradual accumulation of incoming sediment within a reservoir. The process is a result of a complex interaction between the various sediment transport processes that prevail in the river and the surface soil erosion within the basin as well as the hydrodynamics of the reservoir. The available field data suggest a worldwide loss in the storage capacity in the range of 0.5–1%.

There are several methods available to mitigate the sedimentation problem ranging from soil conservation measures to the mechanical removal of sediment. There is a need for a systematic approach that does not compromise the river basin, the river channel, or the reservoir. The lack of an integrated design is one of the main reasons for extensive reservoir sedimentations around the world. No isolated measure can serve as a sustainable method. In addition, mitigation should be viewed in a larger perspective by understanding the socioeconomic aspects. Soil conservation measures should be an inseparable part of a sustainable mitigation plan because they can help to

Reservoir Sedimentation, Figure 9 A schematic of possible impacts of hydraulic structures (dams), morphological and environmental aspects.

preserve the precious topsoil from erosion losses, which is of one the greatest environmental challenges of the twenty-first century.

To model reservoir sedimentation, both the rate of sediment transport at a larger river basin scale and at the river channel scale should be considered. The common approach for modeling soil erosion is to use models that are based on the Universal Soil Loss Equations (USLE). Modeling at river channel scale involves the use of numerical models based on the fundamental equations of motion and continuity. They range from simplified one-dimensional to three-dimensional models. The soil and river channel models yield the sediment load into the reservoir. The sedimentation process in the reservoir is normally estimated using semiempirically based design charts and equations.

The present extensive literature articles and case studies, as well as many useful handbooks, give a very good coverage on various aspects of reservoir sedimentation. However, there is a pressing need for further research. The need is in two areas: one is to gain a better insight into the interaction of the sediment inflow and the hydrodynamics of the reservoir and the second is the use of more-advanced models. Turbidity currents are recognized as a primary sedimentation mechanism. However, there is still a need for addressing the specific physical features of these currents within the reservoir. The latest improvements in numerical modeling make the application and development of advanced numerical models a feasible method for reservoir sedimentation. The availability of various large-scale hydrodynamic, sediment

transport, and water quality models can make the task possible. These models have two major advantages in comparison with those applied so far. The hydrodynamics of the reservoir are more accurately modeled by including the forcing atmospheric conditions. Second, the sediment transport models can account for both multilayer non-cohesive and cohesive sediments. Here, it should be noted that all models, irrespective of their nature and modeling dimension, must be carefully validated and verified. This aspect is especially important for soil erosion models.

Reservoir sedimentation can adversely affect the environment. These effects are apart from technical aspects, such as problems at intake structures and turbines. The possible environmental consequences are water quality problems within the reservoir, increased risk of flooding caused by river aggradation, negative impacts on wildlife, especially various fish species. There will be also a number of morphological and ecological consequences downstream of a dam. There is a pressing need to consider these issues in relation to the impact of possible climate change. In some regions of the world, it is foreseen that climate change may result in significant increase or decrease in surface runoff.

RESERVOIR SEDIMENTATION IN AUSTRALIA UNDER EXTREME CONDITIONS

Hubert Chanson
School of Civil Engineering, The University of Queensland, Brisbane, QLD, Australia

Introduction

Since the early European settlements in Australia, the coastal and continental development of the country has been coupled with the availability of water supply. Today, the country's economy remains highly dependant upon its surface irrigation, and more than 85% of water diversions are for agricultural purposes (irrigation and stock watering only). Any reduction in water storage caused by reservoir siltation, and the associated loss of fertile soil, is a critical parameter with economical and political impacts. There has been, however, some conflicting information on whether reservoir siltation has been significant in Australia. Indeed, for many years, reservoir sedimentation has not been an issue: "the (sediment) yield [...] is relatively low compared to others in the world" (Outhet 1984, NSW Water Resources Commission); the classical text book *Open Channel Flow* by F. M. Henderson, University of Newcastle NSW, made no mention of reservoir siltation in Australia in the section "Sediment transport" (Henderson, 1966). The issue of reservoir siltation in

Australia was ignored and rejected until the late 1970s despite some implications in terms of dam safety (Chanson, 1998; Chanson and James, 1999).

Herein, a reanalysis of existing data and new information on extreme reservoir siltation in Australia is presented. It is shown that several extreme siltation events took place and affected predominantly small to medium size reservoirs. It is the purpose of the study to present new comparative data and to develop new compelling conclusions regarding reservoir sedimentation in Australia.

Hydrology of the Australian continent

Australia is a large continent ($7,690 \text{ E} + 3 \text{ km}^2$) of low relief (Figure 1). Its most prominent topographic feature is the Great Dividing Range, a chain of low mountains and tablelands extending over 2,500 km along the eastern and southeastern coastlines.

Although the average annual rainfall is about 420 mm, the spatial and temporal variability is high. The rainfall may vary from zero for several years during droughts to extreme hydrological events (e.g., 515 mm in 6 h at Dapto NSW, in 1984). The average runoff is only 13% of the rainfall, varying from 0 mm in most Western Australia to over 700 mm in some regions of Eastern Australia and Tasmania (Department of Natural Resources, 1976). Indeed, evaporation is high. Average annual standard pan evaporation exceeds 1,000 mm in nearly all parts of the continent, with extreme evaporation above 3,000 mm in Central Australia.

High evaporation coupled with the variability of surface runoff make conservation and development of surface water resources more expensive, less effective, and more political than in many countries.

Extreme reservoir siltation in Australia

Between 1890 and 1960, more than 20 reservoirs (excluding farm dams) became fully silted in Australia, most in New South Wales (Table 1). The writer investigated personally several reservoir siltation cases (Figures 2–5). Fully silted reservoirs included town water supply reservoirs (e.g., Moore Creek dam), railway dams (e.g., Gap weir), and mining reservoirs (The railway dams were built to supply water to the steam engines for the railway. Steam engines were in use in Australia up to the 1970s.).

Examples of reservoir siltation

Completed in 1888 (first dam) and around 1890 (second one), the Sheba dams were designed to supply water to the gold mines of the Mount Sheba Company, near Nundle NSW located next to the edge of the Great Dividing Range. The upper dam is an earth embankment (7.6 m high, 91 m long), and the reservoir area is 5 acres. The lower dam is also an earthfill structure (6.1 m high, 64 m long) with a 4-acre reservoir area. The dams are located at high altitude, nearly 1,100 m, on the western side of

(*) reservoir fully silted today, (–) information not available.

the Great Dividing Range, and water was collected on both the western and eastern slopes of the Range. The dams are fully silted and used for trout fishing and as touristic attraction. There are some safety concerns because the spillways are inadequate.

Built around 1905–1907, commissioned in 1911, the Pekina Creek dam is an earthfill structure, 24 m high after the heightening in 1914. Located near Orroroo SA, it was designed to supply irrigation and town water. The original reservoir capacity was $1.54 \times 10^6 \text{ m}^3$ (after 1914 heightening), and the catchment area is 136 km^2 . More than 50% of the reservoir was silted in 1944, and the sediment volume accounted for 60% of the initial capacity in 1971. The reservoir was disused in 1964 (McQuade et al., 1981).

The Koorawatha dams, located near Koorawatha NSW, were a railway dams, designed to supply water to the steam engines for the nearby railway line, opened in November 1886 and closed in 1980. Two thin-arch concrete dams were built successively at the same site. The first dam was 5–7 m high, and it is located 5–10 m upstream of the present dam (Figure 2). The crest was still

Reservoir Sedimentation in Australia under Extreme Conditions, Figure 2 Dry reservoir of Koorawatha weir, railway dam completed in 1911 – view from the right bank in December 1997.

visible during dry periods up to the 1930s although, today, it is underneath the dry reservoir bed. Completed in 1911 (or 1913?), the second Koorawatha dam is a concrete single-radius arch (9 m high, 0.92 m thick at crest, 40-m arch radius). The upstream wall is vertical, and the downstream face is battered. The weir was equipped with an outlet system and an overfall spillway (24 m long, 0.3 m high). The reservoir is fully silted today, occupied by sand and gravels, suggesting sedimentation by bed-load (Figure 2).

Completed in 1928, the Borenore Creek dam was built to supply water to the Orange-Broken Hill railway line. The dam is a concrete single-radius arch wall (17 m high, 123 m long at crest, 1.12-m crest thickness) (Figure 4). The catchment area is 22 km^2 , and the original storage capacity was $230,000 \text{ m}^3$. The dam was equipped with an outlet system and an overfall spillway. Interestingly, a new outlet (pipe inlet) was installed, later, about half-height of the dam, as a result of the reservoir siltation which amounted for $150,000 \text{ m}^3$ in 1981 (Figure 4). After being used by the NSW Railway Department, the dam has been used as the town water supply for Molong. The reservoir is used only as an emergency reserve today.

Completed in 1916, the Melton dam is an earth and rockfill embankment, and it was heightened in 1937 and 1967. The reservoir was built for irrigation purposes. The initial reservoir capacity of 21.0 Mm^3 was increased to 23.6 Mm^3 in 1937. The catchment area is $1,098 \text{ km}^2$. During the 1930s and 1940s, the reservoir suffered heavy siltation caused by cattle and sheep grazing, gold and coal mining, and rabbit colonies in the catchment. In 1941, when the reservoir was nearly empty, a heavy rainstorm filled the reservoir in 36 h and the spillway was heavily used. (The reservoir inflow was estimated at $1,444 \text{ m}^3/\text{s}$.) Massive siltation took place during the event, and a 2.6-m thick silt deposit was left on the spillway intake after the flood. In 1945, the reservoir capacity was reduced down to 19.1 Mm^3 . Erosion control works were carried out, including construction of check dams, furrowing works, and elimination of vermin. In 1968, the reservoir siltation amounted for 6.6 Mm^3 of sediments.

The old Quipolly dam or Quipolly dam No. 1 was completed in 1932 to supply town water for Werris Creek NSW, irrigation water and water for steam engines (Figure 5). The dam is a concrete single arch (19 m high, 184 m long crest), the catchment area is 70 km^2 , and the original storage capacity was $860,000 \text{ m}^3$. The reservoir suffered heavy sedimentation between 1941 and 1943 (Chanson and James, 1998). The reservoir was disused in 1955, and the reservoir is fully silted today. The reservoir acts now as a sediment trap for the new Quipolly dam (Quipolly dam No. 2) located downstream.

Comparison between Australian and overseas siltation rates

A comparative analysis of the siltation rates with overseas experience suggests that the reservoir sedimentation

Reservoir Sedimentation in Australia under Extreme Conditions, Figure 3 Fully silted reservoir of Cunningham Creek railway dam (Harden NSW) completed in 1912 – view from the right bank in December 1997.

Reservoir Sedimentation in Australia under Extreme Conditions, Figure 4 Borenore Creek dam completed in 1928 – view from the left bank in December 1997. Note the old scour outlet system and the new water intake at half-height of the dam wall.

rates in Australia were high (Table 2). Table 2 compares the most extreme (well-documented) siltation events in North Africa, North America, Asia, Europe, and Australia. These data are summarized in Figure 6,

showing extreme siltation rates as a function of the duration of the study.

Figure 6 suggests that highest (recorded) siltation rates are observed during short duration studies (1–10 years).

Reservoir Sedimentation in Australia under Extreme Conditions, Figure 5 Fully silted reservoir of Old Quipolly dam (Werris Creek NSW) completed in 1932 – view from the right bank in June 1997.

There is, however, a lack of information on long-term siltation over 70 years. Note further that the data indicate the net sedimentation rate, after flushing. In several cases where flushing was used, the real sediment inflow rate was much larger.

Among the extreme events, the cases of the Shihmen reservoir, the El Ouldja dam, and the Sweetwater reservoir are peculiar. The Shihmen dam (Taiwan Republic of China) is a 133-m high dam built between 1958 and 1964. The maximum reservoir capacity was more than 60,000,000 m³, and the catchment area is 763 km². Although the dam was inaugurated in 1964, the reservoir began filling in May 1963. In September 1963, 20,000,000 m³ of silt accumulated during cyclonic floods (typhoon Gloria).

The El Ouldja dam was a debris dam built to protect the main Oued Djenden dam (Algeria). The siltation of the reservoir was studied in details between 1947 and 1950 (Duquenois, 1951). The results highlighted siltation by bed-load material with sizes ranging from 1 mm to over 0.5 m and heavily loaded turbidity currents of silt and clay (density between 1,100 and 1,300 kg/m³).

Built between 1888 and 1887, the Sweetwater dam was designed to supply irrigation and town water to the San Diego area (USA). The catchment area is 482 km², and the original reservoir capacity was 20 E + 6 m³. Heavy siltation took place during the January 1895 flood, and it was well documented (Schuyler, 1909).

In Australia, the sedimentation of Quipolly reservoir between 1941 and 1943 was an extraordinary event. Overall, most sedimentation problems in Australia were experienced with small to medium size reservoir (catchment area less than 100 km² typically). In contrast, large Australian reservoirs have not been sedimenting rapidly at the exception of Melton and Eildon reservoirs. Heavy siltation at Eildon was experienced in 1940 during torrential rainfalls, following bushfires which destroyed more than 50% of the forest in the catchment (Joseph, 1953).

Today, lower siltation rates are experienced in Australia, especially since the 1950s. It is believed that the reduction in sedimentation is related to the introduction of new farming techniques, new land conservations practices, and an awareness of soil erosion problems. The same trend is experienced in the New South Wales, Victoria, South Australia, and Queensland states (Figure 1).

Discussion: Climatic changes and flushing devices

Interestingly, the records suggest that the most extreme siltation periods in Australia took place during major floods following an El Niño event and long droughts. Such extreme siltation events were experienced at the Junction Reefs reservoir (1902 floods after the Great Drought of 1900–1902), the Moore Creek reservoir (flood of February 1908), the Gap weir (floods of 1919), the Melton reservoir (flood of 1941), and the Quipolly reservoir (floods of 1942–1943).

The drought periods in Australia may be extremely severe. The most severe drought occurred between 1895 and 1903, 1902 being the severest year. During this period, the sheep numbers declined by more than 50% and cattle by more than 40%. Recently, a decade of drought persisted between 1958 and 1968, and between 2000 and 2008.

The world community has focused its attention on the early detection of drought (*El Niño*) which is termed a “major catastrophe” in the television news. But the El Niño phenomenon, also called El Niño Southern Oscillation phenomenon (ENSO), takes place in average every 5–7 years. It is a *recurrent* climate pattern which is not properly managed by local, national, or international institutions. No contingency for long-term policy has been made.

Sediment flushing devices (or lack of)

Surprisingly, the Australian reservoirs have been inadequately equipped with flushing devices (Table 3). Most

(S) Summer rainfall climate, (W) Winter rainfall climate, (F) Important flushing, (*) fully silted reservoir, (?) uncertain data, (–) Data not available.

Australian reservoirs were equipped with a single-scour outlet ($\varnothing = 0.3$ to 0.5 m), inadequate to desilt a reservoir. Only few dams were equipped with two or more flushing systems e.g., the Illalong Creek dam completed in 1914 and now fully silted.

In comparison, the Nabataeans, Romans, and Spaniards equipped their reservoirs with large sediment flushing system. (The Nabataeans were the habitants from an ancient kingdom to the East and Southeast of Palestine that

include the Neguev desert. The Nabataean kingdom lasted from around B.C. 312 to A.D. 106. The Nabataeans built a large number of soil and retention dams. Some are still in use today.) For example, the Roman engineers equipped the Monte Novo dam (A.D. 300, Portugal) with two outlets of 1.2 and 1.4 m² cross-sectional area each. Such an expertise in sediment flushing, gained over the past 22 centuries, was obviously unknown to, or forgotten by, the Australian engineers.

Conclusion

The main findings of the present review are: (1) the reservoir sedimentation has been a major problem in Australia, and (2) the Australian engineers could draw upon local and overseas experience, and from past failures. Indeed several reservoirs (Table 1) became fully silted because the designers did not take into account correctly the soil erosion and sediment transport processes, and no soil conservation practice was introduced.

Today the society expects the useful life of a reservoir to be more over 30–50 years. One lesson from past experience is the need to consider the dam, the reservoir, and the catchment as a complete system which cannot be dissociated. Soil erosion and water runoff lead into the streams some sediment material that is trapped downstream by the dam wall. A total catchment management policy must be considered from the early stage of a reservoir design.

The fully silted reservoirs stand as a source of embarrassment for the scientists and the public (Figures 2–5). Each reservoir failure must be a valuable teaching and pedagogic tool to heighten the awareness of students, professionals and local authorities, and of the public. Society must learn from its mistakes, not to repeat them again!

Acknowledgments

The writer thanks Mr. and Mrs. Chanson, Paris, France, Ms. Chou Y.H., Brisbane, QLD, and Mr. D.P. James for their assistance.

RESERVOIRS IN GREAT BRITAIN

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Introduction

The development of large impounding reservoirs in Britain was mainly due to the necessity of feeding the canals constructed during the first phase of the industrial revolution (1750–1850). It was not until 1868, however, that civil engineers began to carry out research on reservoir storage when the subsequent design of impounding reservoirs replaced the use of early natural lakes for water supply.

Early-nineteenth-century reservoirs almost invariably had earthen embankments with central clay puddle walls, a construction that was known and used before 1800.

Later, impounded reservoirs were formed mainly of masonry or concrete including buttress dams of mass concrete made possible by the invention of Roman cement by Dobbs in 1810 followed by Aspdin's improved patent for Portland cement. These important inventions led to the first British Standard in 1904 (BS 12). The BS stipulated clear requirements with regard to safety measures in design and improved manufacturing techniques. However, the dam disaster in Wales in 1925 led to the Reservoirs (Safety Provision) Act of 1930, which made clear the dangers to reservoirs and the necessary precautions.

Afforestation of catchments started at Oldham in 1885 and has now developed on scientific principles so that today the aesthetic treatment of reservoir catchments is given due consideration in the overall construction of the reservoir.

The record of notable events, improvements, research, and Royal Commissions in the field of reservoirs and water engineering practice in Britain could be said to have extended through nine monarchies: George III (1760–1820), George IV (1820–1830), William IV (1830–1837), Victoria (1837–1901), Edward VII (1901–1910), George V (1910–1936), Edward VIII (1936), George VI (1936–1952), and Elizabeth (1952–present).

Given in the following table are the major reservoirs in operation in Britain (2011) (Table 1).

RESERVOIRS, EARLY BRITISH HISTORY

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Design

Impounding reservoirs in Britain were first introduced during the Industrial Revolution at the end of the eighteenth century for feeding the canals. Reservoirs for public water supplies were constructed early in the nineteenth century, an example being the City of Manchester scheme in the Longendale Valley comprising of seven reservoirs having a gross yield of 150 m³ per day. The construction of these reservoirs was carried out between 1848 and

1877, and the civil engineer was La Trobe Bateman who also designed the Loch Katrine scheme opened in 1859 by Queen Victoria. The Loch Katrine scheme required 70 distinct tunnels over a 34-mile aqueduct to take the water to Glasgow upon which some 44 vertical shafts were sunk for facilitating and expediting the completion of the work. Loch Katrine is a natural loch with drainage area of some 9,393 ha and surface area of 1,315 ha.

The earliest reservoirs were normally formed of dams with a central puddle clay core and shoulders of selected fill. Dam construction has always been a developing civil engineering experience, and today the design of reservoirs is not significantly different from the early days although much has been learned from failures and from the study of soil mechanics. The principal development of earth dams and construction from the middle of the nineteenth century have included the use of concrete for filling cutoff trenches, cement grouting for sealing leaks, dewatering techniques, and modern earth moving plant (Skeat, 1969).

Between 1796 and 1850, 28 earth dams over 15 m high were built for water supply in the British Isles and 141 between 1850 and 1900, three of which were concrete gravity dams. Today, there are some 1,300 dams in the British Isles of which some 90 are hydroelectric supply dams.

Some dam failures have occurred, the more important ones being at Dale Dyke and Dolgarrog. In 1864, the former earth dam for Sheffield failed with the loss of 244 lives. The latter failure was in 1925 with the loss of 16 lives. As a result, the Reservoirs Safety Law of 1930 provided for all reservoirs containing more than 22,700 m³ (5 mg) required a civil engineer appointed by the Government to supervise the design and construction. All reservoirs have to be inspected at least once every 10 years.

Reservoir capacity and yield design rules were first introduced by Hawksley in 1868 and Deacon in 1902 with

further development by Lapworth in 1949, but later as runoff records became available, reservoir design has been based on these records rather on rules. Today has seen examples of river regulation reservoirs where storage is used to augment the river flow at an abstraction point lower down the river. In addition, pumped storage reservoirs have been constructed mainly in the 1970s and 1980s where the direct runoff is augmented by water pumped into the reservoir. The next stage of reservoir development might be estuarial barrages where the whole catchment area is utilized. Such schemes have been proposed for the Wash, the Solway Firth, and Morecambe Bay.

Water treatment

Sand filtration

The treatment of reservoir water by sand filtration was first researched by James Peacock in 1791 and introduced in Paisley by John Gibb in 1804 and Robert Thom at Greenock in 1827. Sand filtration of various types was employed throughout Britain, and in 1940 and 1942, experiments were carried out in Kilmarnock by P.L. Boucher on microstrainers which were then introduced by Glenfield and Kennedy in 1945.

Chlorine

Following the experiments by the reading water engineer Leslie Walker in 1908, in collaboration with the Candy Filter Company, the Reading Corporation installed a full-scale chlorination plant for the treatment of the public supply in 1910, thus becoming the first water undertaking in the country to adopt chlorination as a routine measure (Skeat, 1969).

Coagulation

Coagulation of water with sulfate of alumina began experimentally in 1827 and was used in Bolton for the first time in 1881. Sodium aluminate was introduced from the United States in 1924, and activated silica introduced as a coagulant aid by J.R. Baylis in the United States was first used on a large scale by Warrington Corporation in 1947. Activated carbon is now in general use as a purifying agent for water as a taste remover.

Disinfection

Disinfection by excess lime was first considered by Thomas Clark in 1841, and in conjunction with Sir William Paterson and Sir Alexander Houston, a plant was installed of 31,780 m³/day at Southend Waterworks.

Ozone

Ozone came into Britain from France in 1936, and plants were established at South Staffordshire Water Works Company and Brighten Corporation.

Fluoride

In 1892, Sir James Crichton-Browne concluded that he found some connection between fluoride in the diet and dental caries. However, it was not until 1946 when

fluoride was introduced in the United States that British water engineers decided to consider it for reducing the incidence of dental caries. There was considerable public opposition, however, and today only a minority of water companies have introduced fluoride to the supply.

Softening

About 50% of the British water supply is considered "hard." Experimentation on softening water was carried out by Ruttie (1698–1775), Home (1719–1813), and Henry (1734–1816), but no plants were built until 1841. Thomas Clark (1801–1867) was granted a patent which allowed for the removal of temporary hardness only, but the idea of softening was not favored by the population and even today only a minority of water companies soften the supply. The first softening plant was installed in Plumstead in 1854.

Waterborne diseases in reservoirs

The following diseases associated with water are:

Cholera
Dysentery (bacillary and amoebic)
Gastroenteritis
Paratyphoid
Typhoid
Weil's disease (Leptospirosis).

Examples Epidemics from waterborne diseases not only in Britain but in other countries are:

- London, 1853–1854, outbreaks of cholera 616 deaths – polluted River Thames source untreated.
- Grimsby, Cleethorpes, and Ashbourne, cholera 287 cases and 135 deaths.
- Hamburg, 1892, polluted River Elbe source – cholera, 8,000 deaths.
- Lincoln, 1904, polluted River Witham source – typhoid fever.
- Malton, 1932, polluted well source – typhoid, 23 deaths.
- Chicago, 1933, contamination in the distribution system – dysentery, 1,409 cases, 98 deaths.
- Croydon, 1937, polluted well source – typhoid.
- Huskerville (Lincoln) Nebraska, 1952, poliomyelitis – 20 paralytic cases, 2 deaths.
- Delhi, 1955, hepatitis, polluted River Jumna source – 29,300 cases of jaundice.
- Zermatt, 1963, springs and river sources, typhoid, 437 cases.
- Hong Kong, 1964, well – cholera, 17 cases, 4 deaths.
- Other cases included cholera in Egypt in 1947 in Bengal and Southeast Asia in 1961, and in 1965, cholera spread across the Asiatic region of the former USSR and Iran where 2,943 cases occurred.

It will be noted that most of the above sources were from rivers and wells. Pathogenic bacteria such as *Escherichia coli* do not usually survive in water in reservoirs for more than 30 days. Reservoirs therefore perform

the first stage of treatment and afford dilution and retention of the supply. Reduction of the organic matter takes place by the biochemical oxidation, and physical quality may increase from sedimentation of suspended matter.

RESERVOIRS, MULTIPURPOSE USE OF SMALL RESERVOIRS

Jean Albergel
IRD Representative for East Africa in Kenya/ICRAF,
Nairobi, Kenya

Flood-flow harvesting and small reservoirs

Since ancient times, flood-flow harvesting from valleys, gullies, temporary streams, and its storage in pans, ponds, or small dams have allowed men to manage multipurpose reservoirs. Pans and ponds are dug up to capture and store runoff from surfaces such as hillsides, rocky areas, or rangelands (Mati et al., 2005).

When catchment areas are appropriate and the sedimentation basin is impervious enough, pans and ponds can collect enough water for rural needs such as watering cattle and irrigating crops. Mati et al. 2005, show that a well-designed network of small farm pounds with a good density can improve rural livelihoods by improving food and water security in Sub-Saharan Africa (Figure 1).

However, pans and ponds remain precarious structures because of their small size and risk of drying up, especially in arid climate. Subject to evaporation and to seepage, water in pans and ponds needs to be renewed very often. To control seepage, ponds can be lined with special plastics which dramatically increase their cost. They are also very susceptible to siltation when the rate of erosion is high in catchment areas. In this case, they require frequent maintenance and dredging. They are also subject to destruction when they are overflowed.

Small dams are the more popular method of water harvesting, especially from temporary streams (Figure 2). The dykes of these dams are between 3 m and 15 m high (lowest limit for large dams established by the International Commission on Large Dams). They are built across a stream to form a reservoir in the valley. They are built with earth, stones, or concrete, and located in small rural upper catchments. Small dams have rustically designed lateral spillways with a discharge capacity of some tens of cubic meters per second or even, in some cases, just over 100 m³/s. Some, but not all, have a sluice gate and their unit cost is around 500,000 Euros, sometimes far less. Their reservoirs are relatively small in area

(a few hectares) and have a holding capacity ranging from a few tens of thousands to one million cubic meters (Albergel and Rejeb, 1997). A small dam can be constructed to collect water from few square kilometers (1–10 km²) for a steep catchment to 100 km² for a flat one.

Small dams have been built since the early hydraulic civilizations, Ancient Egypt, Sri Lanka, Mesopotamia, China, and The Roman Empire. In Syria, the dam on the Nahr El Asi near Homs was constructed during the reign of Seti I (1319–1304 B.C.). Many were built at the start of the Christian era (Badieh Dam on the road to Palmyra) (Figure 3). Numerous ruins testify to their presence in the dry steppes. Some still exist but are completely filled with sediment.

In modern times and especially since the second half of the twentieth century, small dams were constructed all around the world, particularly in semi-arid areas. They are often the only possibility to promote development in mountainous (semi-) arid regions. Most of these small reservoirs have multiple uses, including drinking water, fishing, watering livestock, and irrigation of crops. Besides the economic benefits of irrigation and maintenance of livestock, improved access to water promotes health through better nutrition, increased hygiene and reduction of diseases caused by poor hygiene, such as skin infections and eye diseases. Since the 1980s, small dams have been built to protect bigger dams downstream from siltation.

Nowadays, small dams are an important component of landscapes in tropical and mediterranean areas. Their number continues to increase. Numerous and dispersed in the landscape, they structure the rural landscapes and, generate diverse resources. They induce a juxtaposition of often complementary, sometimes competing, and possibly antagonistic actors and practices. They lead to changes in social and institutional rearrangements by new rules on access to resources and ecosystems (Cecchi, 2007).

To assess the benefits and risks associated with these structures, several scientific studies emerged in the late 1990s and early 2000s. These studies, concerned with sustainable development of rural areas, lead to a more general reflection on the ecological and social changes associated with the development of the valleys.

In many tropical and mediterranean countries, studies of the impact of small dams showed positive and negative effects on human health, environment, and socioeconomic development. In some areas, dams have accelerated socioeconomic development (Egziabher, 2003, Albergel et al., 2004a), but other dams have been abandoned because of their deleterious effects on the environment, including erosion, sedimentation (Albergel et al., 2005), and salinization (Laraque, 1991). Many small dams have been installed throughout the world to supply drinking water in rural areas or small towns, especially in areas without groundwater resources (Albergel et al. 2004b). Cyanobacteria are very common in many eutrophic reservoirs and are known to contribute by their blooms to the deterioration in the quality of water (Bouvy et al., 1999).

Reservoirs, Multipurpose Use of Small Reservoirs, Figure 1 Distribution of 908 ponds in Lare Division, Nakuru Kenya (in Mati et al., 2005).

In northern Ethiopia, the construction of small dams has resulted in increased transmission of malaria and bilharzia (Alemayehu et al., 1998; Ghebreyesus et al., 1999). The impact of dams on malaria was far less clear because *Anopheles* is found mainly in the hoof prints of cattle near the tanks, rather than in dams and their infrastructure (Cecchi, 2007).

Small reservoirs: water mobilization for local development function

Runoffs that fill small dams are sometimes generated by a single rainfall event. This event can occur outside the rainy season. Often, the high rate of evaporation from the lakes, together with their shallowness, does not allow the water to be kept for long. Moreover, the submerged banks are often permeable and significant infiltration occurs. Figure 4 shows, for Syndiane Dam in Syria near the city of Homs: (1) the daily precipitation, (2) the levels

of the water in the dam, and (3) the level of siltation. The spillway level and that of the top of the dyke are indicated, making it possible to highlight the discharges. Note the low storage level in 1999, a very dry year throughout the Middle East.

The temporarily stored water can be used in a number of ways. In pastoral areas, small dams provide the water for cattle transhumance. In cultivated areas, they provide water for irrigation, or downstream of the dam, by gravity, or in plots on the banks of the dam by pumping or by using recharge of soil moisture on the banks when the water recedes during the dry season. This cropping system based on the recession of the reservoirs is very common in northeastern Brazil and is called “Vazante” near the “Acudes,” a Brazilian name for small dams. An analysis of the agricultural production systems around 26 hill reservoirs in Tunisia, conducted between 1993 and 1996, gave an understanding of the dynamics of agricultural

Reservoirs, Multipurpose Use of Small Reservoirs, Figure 2 Small reservoir Western Rif (Morocco).

Reservoirs, Multipurpose Use of Small Reservoirs, Figure 3 Roman Dam of Dadieh, road Homs – Palmyra.

Reservoirs, Multipurpose Use of Small Reservoirs, Figure 4 Levels of water in Syndianeh Dam (Syria).

development. It showed that just after the building of the dam (Selmi, 1996):

- 50% of the farmers had not introduced irrigation and were maintaining their traditional system of production.
- 28% were starting to integrate into their system of agricultural production.
- 22% of the farmers currently used small-scale irrigation.

The availability of this water opens the door to new and very profitable speculative activities (in particular, market gardening and fruit-growing) with a gross profit margin up to ten times as high as that of traditional extensive cereal-growing. This optimum use of the water from the hill reservoirs is a source of major additional income, reflected in better living conditions and speculation in land adjacent to the reservoirs.

However, the rapid siltation of some reservoirs has disappointed the farmers. Thus, eight hectares of apple trees planted in the first 3 years of existence of the Sadine reservoir (upper catchment of the Zeroud in Tunisia) are today suffering due to lack of water and at present, are not very productive. 90% of the reservoir's capacity is in fact lost to sedimentation after 20 years.

As the interannual stocks of water held in these storage reservoirs are extremely variable, the idea has been to use them to recharge the phreatic water tables. In Tunisia, Montoroi et al., 2002 provide geochemical evidence of efficient recharge of the alluvial water table by the small dam, and explain the recharge mechanism by the strong infiltrations when the dam is flooded and the water reaches the permeable alluvial terraces. The dam forces the natural system of recharge of the alluvial water tables in the semi-arid zones. Recharge occurs mainly through inundation of the main beds of the waddis.

When climate and hydrology allow permanent impoundment of the reservoir, fishing becomes an important activity for communities bordering the small dams. The fishing effort and the fish production in small dams

of North Ivory Coast represent from 16% to 46% of total freshwater catches (Dacosta et al., 1998). Catches include economically important fish (*Oreochromis niloticus*, *Heterotis niloticus*, *Chrysichthys* spp., etc.) and marketing values indicate that the fishing activity is an important source of currency for the villages.

The first small dams built using modern techniques in Syria were those constructed during the 1960s in the province of Swaida to supply drinking water to villages on a basalt plateau that has no underground water resources. To supply drinking water, the infrastructure needs to be medium sized, with a permanent impoundment and should be well protected from diffuse and accidental pollutions. Nevertheless, a serious monitoring of plankton and water quality must be performed to prevent supply to drinking water faucets during cyanobacterial bloom. In 1996, a cyanobacterial bloom occurred in the water supply for a hemodialysis center in Caruaru (Brazil). Despite extensive pretreatment (sand, carbon, resin and microfiltration), more than 117 of 136 patients (86%) experienced symptoms, and 75 patients (55%) died from the incident.

Other socioeconomic benefits of small reservoir projects are tourism, infrastructure development, employment opportunities, alleviation of poverty, and improved living conditions. Near large towns, there are holiday homes at the sites of small dams and the lakes are used for leisure activities. Such is the case with the small dam at Al Corane, not far from Damascus in a small high valley with cool weather in summer time.

Small reservoirs: erosion control and infrastructure protection function

North African countries developed a large hydraulic infrastructure in the 1970s and 1980s. Almost all the large dams are affected by significant sediment. Numerous small dams have been built to slow down siltation of the largest downstream reservoirs. The idea is to capture sediment, which is essentially produced by upstream sloppy zones, in small and relatively inexpensive reservoirs.

The construction of small dams at different points of the hydrological network attenuates the flood wave and reduces the erosion dynamics of the runoffs.

For example, the largest dam in Morocco, the Al Wahda Dam on the Ouergha River in the province of Sidi Kacem (88 m high, with a capacity of $3.4 \cdot 10^9 \text{ m}^3$), is protected by many small dams in the upstream catchment designed to hold the erosion coming from the steep marly slopes of the Rif. Some have already been constructed, while others are planned. Erosion from the Ouergha catchment, estimated at 98 tones ha^{-1} annually over 6150 km^2 , causes the dam to lose a volume of $60 \cdot 10^6 \text{ m}^3$ each year (IAASTD, 2008).

An assessment of siltation of 26 small reservoirs was performed in the mediterranean countries during the HYDROMED program (1996–2000) (Albergel and Nasri, 2001). Siltation relative to the area of small dam

catchment ranges from $1.1 \text{ m}^3/\text{ha}/\text{year}$ (or $1.8 \text{ t}/\text{ha}/\text{year}$), for a fairly wooded piedmont catchment where a lot of erosion control work has been done (El Gouazine in Central Tunisia), to $31 \text{ m}^3/\text{ha}/\text{year}$ (or $50 \text{ t}/\text{ha}/\text{year}$) for a small, very marly catchment in the pre-Rif hills of Morocco: the Saboun Dam.

A hydrological model to reconstitute the solid transport for each flood event was performed. It provided a better understanding of the erosion and of its consequences on the siltation of the reservoirs of small dams. Figure 5 shows the results of this model for Kamech Dam in Tunisia. It can be seen that siltation is associated with extreme events. Three floods were responsible for 50% of the solid transport over a 9-year period of observation (27 February 1996, 18 January 1999 and 29 November 1999). The last contributed to 20% of the sediment transport noted over the period (Albergel et al., 2004a, b).

Reservoirs, Multipurpose Use of Small Reservoirs, Figure 5 Model to simulate sediment transport flood by flood, Kamech Tunisia.

Small reservoirs: environmental impacts

Environmental impacts of large dams are well studied and quantifiable, while small dams have generally been perceived as benign, and their environmental impacts are rarely the subject of extensive studies.

The oases effect of small dams in dry areas is often quoted as the more positive environmental impact of small reservoirs. The aquatic vegetation that grows in the reservoirs provides a suitable habitat for wetland fauna (batrachians, water snakes, water tortoises, and shellfish).

The banks of reservoirs, often replanted with trees, are nesting and protection sites for birds. The Fuligule Nyroca, a rare species in North Africa and included in the list of protected species in Tunisia, nests at the hill reservoir at Cherichira (Central Tunisia). (Azafzaf and Hamrouni, 2002).

Small reservoirs, and their multiplication in the landscapes, also have significant adverse effects in particular the accumulation of sediments, salinization in some cases, and they increase the transmission of waterborne diseases, such as bilharzia, malaria, and diarrhea. Planning, construction, and rehabilitation of small reservoirs are usually done by communities and there are no systematic assessments of their impact on health and environment.

The environmental risks most often mentioned for dams are the consequences of dam failures. Despite their low load, small dams have a mean failure rate of the same order as for large dams. As there are at least 50 times as many small dams as large ones, a few dozen small dams are destroyed each year (Lemprière, 1993). When the dam has a storage capacity of 50,000 m³, its destruction goes unnoticed. It causes few disasters downstream, even though from the point of view of solid transport, the sediment stocked in the reservoir is released into the water system, and the erosion dynamics resume. When the dam is 10 m to 15 m high, with a storage capacity of a few hundred thousand cubic meters, its failure can create dangerous floods of several hundred cubic meters per second. As a large number of people may have set up homes since the dam was constructed, the dam failure can be catastrophic.

Conclusions

Small dams are structures that have their own characteristics and that can supplement a policy of water resource mobilization. They have an important role in the development of agricultural land and are the focal points for local agricultural development. Rapid silting of the reservoirs acts as a brake on agricultural development.

Storage reservoirs are good sediment traps. They protect downstream infrastructures and can prolong the life of a larger dam located downstream. Recharging the alluvial water table is in many cases a realistic objective, but an appropriate dam site must be chosen.

From an environmental point of view, the impacts are positive. They create small wetland areas, contributing to biological diversity and the protection of birds and other animals. The major environmental risk is dam failure.

The choice of location of a small reservoir must be consistent with precise objectives that are either of conservation and downstream protection or deliberately oriented toward development. In the first case, the conservation objective must be clearly defined. For instance, to protect a large dam, a certain number of reservoirs are required upstream. They have a limited life expectancy, but when they are completely silted, they will serve as small deltas to spread the water and attenuate the flood waves. During the lifetime of the structure, it is possible to plan for afforestation which only requires irrigation the first 3 years. The cost of a small dam to provide water to young trees is comparable to that of transporting the water by tanker.

With the development objective, the sustainability of the resource is the main priority, and erosion control work not affecting the water inputs should be carried out on the slopes as soon as the small dam is built. Water management then introduces the issues of liability, shared rights, and shared responsibilities for the maintenance of a collectively owned, renewable natural resource.

RESTORATION OF URBAN LAKES IN THE NE MUSI BASIN, HYDERABAD, INDIA

V. V. S. Gurunadha Rao
 Environmental Hydrology Group, National Geophysical Research Institute (Council of Scientific & Industrial Research), Hyderabad, India

Lakes in NE Musi basin

Hyderabad Urban Development Authority under Green Hyderabad Program has plans to restore about 85 urban lakes in Hyderabad. As a first step, they have identified five lakes for assessing the groundwater–lake water interaction for design of sewerage treatment plants (STP). Among the six lakes in NE Musi basin around Hyderabad, viz, Patelcheruvu, Peddacheruvu, Nallacheruvu, RK Puram Cheruvu, Nadimicheruvu (Safilguda), and Bandacheruvu lakes, an STP is already functioning at Nadimicheruvu. The watershed covers an area of about 38 km² (Figure 1).

Urban lake water restoration methodology

Among the parameters of interest for understanding lake water quality are biochemical oxygen demand (BOD) and chemical oxygen demand (COD), dissolved oxygen (DO), total nitrogen (TN), and total phosphorous (TP). Periodical measurements of lake water are important to characterize the changing water quality with respect to inflows as a result of monsoon and non-monsoon periods. The characterization helps to compute the status of lake in terms of nutrient load whether a lake is pristine (oligotrophic) or eutrophic. The nutrient parameters TN and TP are useful for the computation of trophic status index (TSI), and further, the status decides which is the limiting parameter for eutrophic status in the lake (Carlson, 1977). The sediments also show adsorbing capacity of nutrients, which has to be estimated through monitoring of sediment samples for nutrient status. The sediment status decides the need for dredging of lake bed for removal of phosphates as the remediation of phosphate in lake environment is through only sediment disposal.

Further, a bathymetric survey of lake bottom surface will help computation of lake storage capacity. Bimonthly monitoring of inflow and outflow measurements on the inlet and outlet channels of lake helps compute the lake residence time, which is an important parameter for taking up lake cleaning operations. The residence time decides how much time is needed for cleanup of a lake. The measurement of evaporation loss from the lake surface determines the potential loss. In addition, an important component in lake water budget is the groundwater component. The groundwater component plays a vital role, depending on the position of a lake in the watershed, namely, recharge area or discharge area.

For understanding the lake water and groundwater interaction, a groundwater flow model based on physical framework, hydrogeological parameters, inflows/outflows into lakes, height of lake water column, and groundwater withdrawal within the watershed has to be estimated. A groundwater balance has to be computed through the zone budget from the model after calibration (Gurunadha Rao et al., 2004). Further, if likely contamination from the lake is expected, a prognostic scenario depicting source loading in the lake water as well as other activities has to be incorporated in the mass transport model. The contamination of nitrates from the lake water in a watershed helps arresting spread of contamination. Lakes in NE Musi basin study have been illustrated to explain the need for a comprehensive study for lake restoration programs in the urban environment.

Water quality of lakes in NE Musi basin

The surface water quality measurements carried out in all the six lakes (Figure 1) indicate that the BOD concentration in surface water of six lakes is varying from 10 to 70 mg/L during October 2002 and 2003 – 38–169 mg/L during June of 2003 and 2004. The maximum BOD has been found in Peddacheruvu and Nallacheruvu lakes and

Restoration of Urban Lakes in the NE Musi Basin, Hyderabad, India, Figure 1 Location map of lakes in Northeast Musi basin, Hyderabad.

also has been reported in the earlier studies (APPCB, 2001). The minimum values have been found in Nadimicheruvu due to entry of treated wastewater entering the lake. The average COD concentration in the lakes varies from 140 to 450 mg/L during the study period (Figure 2).

Nutrient load in terms of total nitrogen (TN) and total phosphorous (TP) has been estimated in the lake water as well as from the sediments. The TN concentration in lake water is found varying from 0.2 to 90 mg/L during the study period. The minimum TN values have been reported from Nadimicheruvu <10 mg/L and maximum from Nallacheruvu. The TP concentration in lake water has been varying from 0.2 to 30 mg/L. The minimum value of TP has been reported from Nadimicheruvu and maximum value from Peddacheruvu. The sediments are

also found adsorbing the TN and TP, and their enrichment and depletion depend on the lake water conditions. There is cyclic behavior and enrichment during summer months and depletion during rainy season noticed during the study period. This cyclic behavior, particularly for TP, can be controlled through dredging of lake bed sediments. TN and TP concentrations in sediments are found varying from 0.9 to 136 mg/kg and 4.6–343 mg/kg, depending on the period of observation. Enrichment of TP and TN concentrations in sediments has been noticed during October. Depletion in TN and TP concentrations in lake bed sediments has been reported during the month of February (Gurunadha Rao et al., 2005).

Trophic status index (TSI) is a measure expressing the lake water quality based on nutrient inputs, based on TN and TP values (OECD, 1982). The TSI based on TN

Restoration of Urban Lakes in the NE Musi Basin, Hyderabad, India, Figure 2 BOD and COD (mg/L) in lakes of NE Musi basin during Oct 2002–Oct 2004.

concentrations is varying from 33 to 121. The TSI based on TP concentrations is varying from 81 to 153. The TSI implies that the lakes are mostly phosphate-limited compared to the nitrates. The conditions indicate that lakes are under hypereutrophic condition and demand dredging of lake sediments for phosphate remediation.

Lake water budget

The storage capacity of lakes computed from the bathymetric survey carried out during June 2005 after rising the bunds indicates that Patelcheruvu can hold 115 million liters (ML) at FTL (full tank level). The bathymetric survey carried out during 2003 indicated that Peddacheruvu

could hold 368 ML and Nallacheruvu storage volume being 226 ML at respective FTL. The Patelcheruvu will have a residence time of 1.5 days, Peddacheruvu will have a residence time of 8.8 days, and Nallacheruvu will have a residence time of 8.7 days. Thus, these lake's residence times are found to be <10 days. A groundwater flow model has been constructed, and groundwater balance was computed using zone budget (McDonald and Harbaugh, 1988; Guiger and Franz, 1996). The computed seepage losses and suggested STPs capacity for tertiary treatment at individual lakes in the NE Musi Basin are shown in Figures 3 and 4, respectively.

Water budget has been computed with an average actual evaporation loss of 4.5 mm/day from lake water surface at full tank level of Patelcheruvu, Peddacheruvu, and Nallacheruvu are 11 ha, 17 ha, and 17 ha, respectively. A groundwater flow model of the NE Musi Basin computed the zone budget of each lake in the watershed. An STP of 0.6 MLD capacity for tertiary treatment has

been functioning on Nadimicheruvu. The lake surface area is about 10 ha, and evaporation loss at 4.5 mm/day from the lake water surface works out as 0.45 MLD. As the lake is situated in recharge area of the watershed, it contributes about 1 MLD to the groundwater (Gurunadha Rao et al., 2005). Under lake restoration program, it is envisaged to maintain FTL Nadimicheruvu, then it needs a supply of 1.5 MLD of treated wastewater. On a conservative basis with allowance for some outflow from the lake, an STP of 2 MLD capacity is required. It is recommended to enhance capacity of the STP to 2 MLD at Nadimicheruvu based on lake water and groundwater interaction (Figure 3).

Establishment of STPs for tertiary treatment and a wetland for nitrate removal and dredging of lake bed for phosphorous removal seems to be the best management practice implemented under urban lakes restoration program. However, minor modifications in the capacity of STPs are needed in view of lake water interaction with

Restoration of Urban Lakes in the NE Musi Basin, Hyderabad, India, Figure 3 Computed seepage loss from GW flow modeling: Lakes in NE Musi basin.

Restoration of Urban Lakes in the NE Musi Basin, Hyderabad, India, Figure 4 Suggested capacity of STPs at individual lakes in NE Musi basin.

groundwater playing a vital role in lake water budget and in addition to the surrounding urbanization. The surplus inflows to lakes above the STP capacity have to be diverted through separate surface runoff carrying channels bypassing the lakes.

RIVERINE THERMAL BAR

Eddy Carmack
Fisheries and Oceans Canada, Institute of Ocean Sciences,
Sidney, BC, Canada

Synonyms

Convergent frontal zone; Downwelling plume

Definition

Riverine thermal bar. A frontal interface and downwelling plume of fresh water at and near the temperature of maximum density (T_{md}) that is formed by the confluence and mixing (cabbelling) of lake and inflowing river waters with temperatures on opposing sides of the T_{md} . The riverine thermal bar (RTB) forms in temperate lakes during spring and autumn overturn and is a special case of the classical thermal bar (TB) that is formed by differential heating/cooling of inshore and offshore waters during spring and autumn transition.

The riverine thermal bar

The thermal bar (TB) is a system-wide convective phenomenon affecting lake overturn in deep temperate lakes that is formed by the confluence of the parent water parcels on opposing sides of the temperature of maximum density ($T_{md} \sim 4^{\circ}\text{C}$). When two such parcels mix, the resulting product is denser than the mean density of the two unmixed components, a process is known as “cabbelling” (see Foster, 1972 for a discussion and etymology). The resulting downwelling plume and overturning circulation cells maintain surface convergence and frontal zone structure. The classical TB (see Tikhomirov, 1963; Rodgers, 1965) forms within a lake with sloping bottom owing to differential heating (in spring) or cooling (in autumn). The riverine thermal bar (RTB) is the special case, whereby an incoming river supplies water on the opposing side of the T_{md} to that of the lake; the resulting juxtaposition and mixing of the lake and inflow results in cabbelling and subsequent sinking of the denser mixtures (Carmack, 1979).

Formation of the RTB rests on the differential warming and cooling of river and lake waters during the spring and autumn transitions. Owing to their shallower depths, incoming river waters will respond more rapidly to spring heating and fall cooling than those of the recipient lake and will thus pass through the surface T_{md} earlier (Carmack et al., 1979). An idealized spring overturn sequence for a riverine temperate lake is shown in Figure 1. In winter, both the lake and the incoming river are colder than $^{\circ}\text{C}$ with the river being somewhat colder and less dense than the lake and so it spreads as a buoyant plume at the lake’s surface (Figure 1a). With the onset of spring, the shallow river warms more rapidly than the lake and, upon reaching 4°C , sinks as gravity current to the lake’s bottom (Figure 1b). Further warming of the river above 4°C creates the antithetical condition,

Riverine Thermal Bar, Figure 1 Schematic of spring overturn in a temperate lake progressing from (a) winter conditions with both the lake and the incoming river are colder than $^{\circ}\text{C}$ and with the river colder than the lake, (b) the onset of spring with river warming to 4°C before the lake, (c) warming of the river above 4°C before the lake so that mixing creates the spring RTB, and (d) both river and lake temperatures above 4°C so that the river plume spreads across the surface.

whereby the river water initially spreads at the lake’s surface but sinks as a downwelling plume as it mixes with ambient lake water, thus creating the spring RTB (Figure 1c). Finally, when the entire lake warms above 4°C , the river plume spreads once again across the surface of the lake (Figure 1d). The same sequence occurs in reverse during autumn as the river cools more rapidly than the lake. Horizontal density gradients are established on both sides of RTB which, under geostrophic balance, force a counterclockwise circulation in the riverward domain and a clockwise circulation in the lakeward domain (cf. Holland and Kay, 2003).

The dynamics of the RTB may also be influenced by the differential compressibility of water, the so-called thermobaric mechanism (Carmack and Weiss, 1991). Because cold water is more compressible than warm water, T_{md} decreases with increasing depth (by about $0.021^{\circ}\text{C} \cdot \text{bar}^{-1}$). In very deep lakes this may affect the dynamics of the descending plume in that the core of the descending plume will continually shift toward its colder side; thus, lakeward during spring overturn and riverward during autumn overturn.

The RTB has important ecological pollutant dispersal consequences (Carmack et al., 1979; Holland et al., 2003). On the seasonal timescale, it is a major transport mechanism driving whole lake convection, ventilation, and nutrient renewal. During periods when the RTB is active, converging flow at the RTB constrain cross-frontal exchange. Thus, the RTB acts as a barrier separating lakeward and riverward domains. In spring, two distinct

phytoplankton grown regimes are found, with higher production rates inshore and maximum biomass accumulation at the convergent front.

RUSSIAN LAKES

Nikolai Filatov¹, Tatyana Gronskaya²

¹Northern Water Problems Institute, Karelian Research Center, Russian Academy of Sciences, Petrozavodsk, Karelia, Russia

²State Hydrological Institute, Saint-Petersburg, Russia

General information

Russia, with an area over 17 million km², is situated in the arctic, subarctic, temperate, and partially in the subtropical climatic belts of the northern part of Eurasia (Large Atlas of Russia, 2005). Russia has over 2.8 million lakes of various origin, 98% of them are lakes with a surface area less than 1 km². Lakes of Russia belong to the drainage basins of 12 seas and three oceans. An overwhelming majority of lakes in Russia are freshwater lakes, but there occur *brackish, saline, and bitter-saline lakes* in the south of its European territory and in southern Siberia. Freshwater lakes contain a total of 26,500 km³ of water (State Report, 2009). Many large lakes are regulated (Baikal, Onezhskoye, Imandra, Belaye, etc.). Russia partially contains the world's largest lake – the Caspian Sea (surface

area 371,000 km², Kara-Bogaz-Gol Gulf excluded), the deepest lake – Baikal (1,741 m), and the largest lakes of Europe – Ladoga and Onego.

Genesis of lakes

The basins of Russia's largest lakes are mainly of *tectonic* (Baikal, Teletskoye) or *glaciotectionic* genesis (Ladoga and Onego). The group of *glacial* lakes, which are the remains of periglacial reservoirs, comprises such lakes as Il'men, Chudsko-Pskovskoye, as well as *morainic* lakes, of which Seliger is the largest.

Sinkhole lakes in Russia are subdivided into *karst*, *suffosion*, and *thermokarst* ones. *Karst* lakes (small size) occur in areas with dolomitic limestone and gypsum: Onega and Northern Dvina interfluvium, between lakes Onego and Beloe, in the Upper Volga, Ural, Caucasian regions, Tatarstan, and a number of other regions. *Suffosion* lakes are most widespread in the south of West Siberia. The most numerous group is of the *thermokarst* genesis and comprises tens and hundreds of thousands of lakes in the tundra permafrost zone.

The floodplains and estuarine parts of large rivers like Volga, Pechora, Kuban', Amur, Lena, Vilyuj, etc. typically contain *oxbow lakes*. *Volcanic lakes* are located in volcano craters in Kamchatka and Kuril Islands, where one finds also *landslide-dammed lakes*. *Tarns* occur in the Caucasus Mountains. *Liman- and lagoon-type* lakes are plentiful along the coasts of the Sea of Azov, Caspian Sea, as well as the Arctic and Pacific Oceans.

Major lake regions and largest lakes

Let us briefly describe the main lake regions and largest lakes of Russia (Figure 1) relying on the classifications proposed by Sokolov (1952), Domanicky et al. (1971), and in the papers Water Resources (2008) and State Report (2009).

Table 1 shows the principal morphometric characteristics of the country's largest and most economically significant lakes. The largest lake regions are the Northwestern, Caspian, West-Siberian, North-Siberian, Transbaikalian, Amur, and Kamchatka areas.

The Northwestern lake region of Russia covers the territory of the Kola Peninsula, Karelia, Leningrad, Pskov, Novgorod, Tver, and Vologda Oblasts. In addition to small and medium-sized lakes, the Northwestern region comprises the great lakes such as Ladoga and Onego (See *Ladoga Lake and Onego Lake (Lakes Ladozhskoye and Onezhskoye)*), Chudsko-Pskovskoye (shared with Estonia), and many reservoir lakes such as Imandrovskoye (former Lake Imandra), Vygozersko-Onedskoye, Topo-Pyaozerskoye, and others.

Karelia is the richest in lakes which cover a total of about 21% of its area (Filatov and Litvinenko, 2001). Karelia is situated in the eastern part of Fennoscandia. There are more than 61,000 lakes of two major genetic types: tectonic and glacial. The lakes with an area of less than 1 km² predominate. Only 1,389 lakes (about 2% of

Russian Lakes, Figure 1 Lakes and lake regions of Russia.

the total number) are larger than 1 km². The water quality is preconditioned by weak buffering capacity of granites and gneisses, considerable accumulation of humus, low mineralization of the water with low calcium and magnesium concentrations, and often high humus concentrations. About 35% of Karelian lakes have mesohumic waters, 20% of lakes are rich in organic matter. Low-humus waters also account for about 20% of all waters. Hydrogen activity varies from pH 4.07 to 8.34. The lowest pH values (<5.5) occur in highly water-logged areas and in small lakes supplied with atmospheric nutrients. Most of the lakes are oligotrophic (up to 12 mg/l of total phosphorus) or mesotrophic (8–25 mg/l). The lakes are inhabited by almost 700 species and forms of phytoplankton and periphyton, 652 zooplankton, and 138 planktonic protozoan taxa, together with 1,500 species and forms of benthic animals and 54 fish and fish-like animal species.

The Kola Peninsula has about 100,000 lakes contained in tectonic erosion depressions of Fennoscandia. Lakes cover about 10% of the territory. Their waters are fresh or ultra fresh, with a mineral content of 10–30 mg/l and less than 1 mg/l of suspended solids. Many small lakes in the region are acidified because of the low buffering capacity of the catchments and heavy human impact. The largest lake of the Kola Peninsula, *Imandra*, has been converted into a long-term reservoir lake. The natural regime is maintained in Lake Umbozero. For seasonal level variations, there are 1.2 m. The lake freezes over in late October to December and breaks up in late May–June. Lakes of the Kola Peninsula are polluted by wastewaters from numerous industries and by contaminated precipitation. Due to human impact, water transparency in Lakes

Imandra and *Umbozero* dropped from 6–8 m to 3–4 m over 50 years. Most of small lakes are oligotrophic. Waters in the large Lake *Imandra* are meso- and eutrophic; the Kola nuclear power plant operates at the lake (Moiseenko and Gashkina, 2010).

Lake *Il'men* is the fourth biggest lake in European Russia. It belongs to the *Ladoga* Lake drainage basin and features substantial inter-year (up to 7.4 m) and intra-year (187–537 cm) level fluctuations. The lake area varies from 733 to 2,090 km² (Gronskaya, 2008). The ice-covered period lasts from late November to late April. High organic matter content makes the lake water yellowish brown or greenish – during blooms. The lake is the source of potable, industrial, and agricultural water supply – rich in fish. The *Volkhov* River, which originates from the lake, drives the hydropower plant situated 27 km away from the mouth. The plant has no significant effect on the lake level. *Chudsko-Pskovskoye* (*Peipsi-Pihkva* in Estonian) is the European fourth biggest freshwater lake. It is made up of three parts, each having its own name (Noges, 2001). The water is fresh, little mineralized, transparent down to about 2.5 m. The lake freezes over in late November to early December and breaks up in late April to early May. Relative retention time is about 2 years. It supports navigation, commercial and amateur fisheries, and recreation. The shores abound in cultural monuments (churches, monasteries). The main problem for *Chudsko-Pskovskoye* Lake is eutrophication.

Scenic Lake *Seliger*, featuring very complex configuration, lies in the centre of European Russia. It is made up of a number of lake pools connected by short channels. The lake usually freezes over early in November and breaks

up in mid-April. Its use comprises recreation, passenger traffic, and fisheries.

Several large lakes – Vozhe, Lacha, Kubenskoye, and Beloye – lie in the north of European Russia in Vologda and Archangelsk regions. Lake Vozhe is connected to

Lake Lacha. The multiannual range of the lake water level fluctuations is 1.6 m. Water “blooms” are nearly annual on these lakes. The ice-covered period lasts from mid-November to early May. Lake (reservoir) Kubenskoye is a part of the Volga–Northern Dvina waterway. The lake

freezes over in early November and breaks up in late April. It serves for navigation, fisheries, and recreation. In its natural condition, Lake Beloye had a surface area of 1,290 km² and 5.2 km³ of volume. In 1964, it became a part of Sheksninskoye reservoir. Surface area of the lake at flood-control storage elevation is 1,670 km², full capacity is 6.52 km³. The lake is a part of the Volga–Baltic waterway (Water recourses, 2008). The reservoir freezes over early in November, breaks up late in April, and is used for navigation, power generation, water supply, and recreation.

The Caspian lake region comprises numerous lakes of the Caspian lowland, Volga–Akhtuba floodplain, and Volga delta. This region extends further eastward to north-west Kazakhstan. Playa lakes, which usually form in depressions that are mainly filled with meltwater and river overflows, are widespread there. Average percent cover of lakes in the region is 1–2%, but in the Volga and Terek deltas, it grows to 11% and 12%, respectively (Domanicky et al., 1971). The region has some large, mostly seepage lakes, e.g., Elton and Baskunchak. The climate being arid, the majority of lakes in the region are saline or bitter-saline. Lake Elton – a saline (200–500 PSU), seepage lake – is the biggest saline lake in Europe and one of the world's most mineralized lakes. Water mineralization is 1.5 times that of the Dead Sea. The water contains algae *Dunaliella salina*, which make its color look reddish. The bottom holds salt deposits overlain by mineral hydrosulfuric mud. The lake is comparable with the Dead Sea in its medicinal properties. The Lake Baskunchak salinity is ~300 PSU. The surface salt deposit of the lake is 10–18 m thick. Annual salt mining is 1.5 to 5 million tons, i.e., about 80% of Russia's total.

The Azov–Black Sea region has many liman-type lakes (Domanicky et al., 1971). The biggest *Beysug liman* of the Sea of Azov is used for recreation and fisheries.

Between the Caspian Sea and the Sea of Azov, there lies a large lake Manych-Gudilo (Matishov, 2005), which is now the eastern seepage lake section of the Proletarskoye reservoir. It was impounded in 1932; water mineralization is up to 40 g/l. The lake's fishery value has been lost. A strict nature reserve is located there.

In southern forest-steppe areas of European Russia, the Ural region and the Caucasus lakes are scarce.

Five lake regions are distinguished in the Asian part of Russia (Siberia and Far East). The West-Siberian lake region falls into two subregions: Northern and Southern. The Northern subregion comprises lakes of forest tundra and forest-wetland landscapes of the West-Siberian lowland. The territory contains over 680,000 lakes, only 8,500 of which are bigger than 1 km². The lake cover of the territory is 3.8%. Several lake groups are distinguished in the Southern subregion: Barabinskaya (the biggest lake Chany), Kulundinskaya (including large Lake Kulundinskoye), and Ishimskaya steppe lakes. The percent cover of lakes is high also in the eastern foothills of the Urals (up to 10–14%). In addition to freshwater lakes, there are many saline ones, some are of value for

balneology and fish farming. This subregion features highly mineralized seepage lakes, many of which are saline or bitter-saline. Given the modern surface area of Lake Chany, the lake cover of the territory is 2.3%. Lake Chany is a seepage lake with brackish water. Its area varies substantially due to intensive utilization of river water resources and to climate variations (1,400–2,000 km²) (Fluctuated Lake, 1984). The lake is made up of a number of pools. To preserve the bulk of the lake, the Yudinsky pool was cut off in 1978. The pool is now nearly dry. The lake freezes over in the second half of October to the first half of November and breaks up in May. It is used for fisheries and water traffic. The region contains the large Lake Kulundinskoye, with a channel connecting it to the bitter-saline Lake Kuchuk (181 km² and a max depth of 3.3 m). The lake does not freeze over in winter. The bottom is silted, with a layer of mirabilite (up to 2–2.5 m).

The scenic mountain Lake Teletskoye lies in the south of West Siberia in the immense tectonic basin, surrounded by mountains 2,000–2,500 m high. Its transparency (Secchi depth) is up to 15 m (Physical-Geographical 2008). This lake is the only freshwater reservoir in Siberia with no permanent ice cover. Ice thickness is 30–40 cm, reaching 70–102 cm on harsh winters. Max level fluctuations range is 605 cm. The lake is little mineralized (78 mg/l), ultra-oligotrophic. It is similar to Lake Baikal in origin, catchment and bed geology, climate, and hydrochemical regime. Tourism is developing on the lake and in its catchment.

The periodic drainage freshwater lake Ubinskoye is also located in this region. It is mainly fed by wetlands. In the mid-twentieth century, the lake was famed for plentiful fish.

The North-Siberian lake region is represented by lakes of the West-Siberian tundra zone and North-Siberian, Yana–Indigirka, and Kolyma lowlands – northern slopes of the Putoran mountains. The region has a total of over 600,000 lakes and some 12,600 lakes bigger than 1 km². Lake cover varies from over 10% in River Lena delta and 5–10% in the West-Siberian zone and Rivers Yana–Indigirka lowland to 3–5% in the rest of the region. The region's largest lake is Lake Taymyr. A 1.5-m fall of the water level diminishes the lake surface area to 1,200 km² (Geography, 1985). It is located in the permafrost zone, being a part of a strict nature reserve. The ice cover exists from late September to July, with max ice thickness of 2.5 m. Its flora and fauna consists of the marine aquatic organism complex, as well as species typical of Baikal.

Noteworthy are large lakes Kungasalakh and Portnyagino near the Gulf of Khatanga and lakes Khantaiskoye, Keta, Lama, Melkoye, and Pyasino to the south of it.

Lake Khantaiskoye is the second deepest lake in Russia after Baikal. It lies in a narrow tectonic basin. Lake Pyasino is of glacial origin, with locally waterlogged shores. The lake collects water from large lakes such as Lama, Keta, and Glubokoye. Lake Keta is transparent down to 11 m. Its uses are tourism and amateur fishing.

Lake Lama is connected with Lake Melkoye. Ice thickness is 80–100 cm, shallow, with level fluctuations about 4.7 m. Lakes in the region freeze up early in October and break up in late June to early July.

The Circumpolar Maritime lake region (Domanicky et al., 1971) comprises the lake-rich tundra zone of the Arctic Ocean coast. The lakes are predominantly of thermokarst genesis. The largest saline lake Mogotoevo is connected to the East Siberian Sea via a channel.

The Transbaikalian lake region comprises 50,000 diverse lakes, including Russia's largest freshwater lake – Baikal. Other reservoirs to be mentioned are Eravinskiye and Arakhleyskiye groups (mainly freshwater drainage lakes) and Lakes Zun-Torey and Barun-Torey, which may dry out in low-water periods. The region's lake cover, including Lake Baikal area, is 3.9%. Zun-Torey is a saline seepage lake reaching 300 km² on high-water years and nearly vanishing on dry years. When full, it becomes connected to Lake Barun-Torey – seepage, saline, intermittent lake partially located within the Daurisky nature reserve. It is frozen from November to April, down to the bottom in winter. A small part of the large lake Ubsu-Nur (total area 3,350 km²) is situated in Russia, on the border with Mongolia. Ice covered from October to May, it has high salt content (up to 18 g/l), with sulfate and sodium ions.

The Amur lake region comprises lakes of the River Amur drainage basin, downstream of the Shilka and Argun' river confluence. The biggest lake is Khanka. The region also harbors many fairly big lakes more than 250 km² in area, including those connected via channels to Amur, and fed by the river during floods. The region's lake cover, including Lake Khanka (shared with China), is 1.1%. Lake Khanka is the largest freshwater lake in the Far East of Russia, shared by Russia and China. Its water is moderately polluted, and metal ion content is high. The lake harbors many fish and aquatic invertebrate species, including many endemics (State Report, 2009). Lakes Bolon, Udy, Orel, and Kizi are connected to the Amur River via channels, and their water quality during floods depends on the Amur water quality. They are ultra-freshwater lakes with 35–149 mg/l mineral content, pH 5.8–8.8, and high nutrient concentrations. Lake Chukchagirskoye features high content of suspended solids, which settle down in winter. Its organic matter content is high, with mineralization of 30–80 mg/l. It is ice covered from late October to early November to May.

The Kamchatka lake region contains more than 40,000 lakes, of which 199 are larger than 1 km². Lakes of the region are quite diverse (Sokolov, 1952) including the so-called volcanic lakes – the largest ones being Kurilskoye and Kronotskoye – as well as lagoon-type lakes such as Nerpichye, in Kamchatka River mouth. Percent cover of lakes is 1.1%.

There are volcanic lakes (*caldera type*), e.g., Lake Kurilskoye holds the largest cockeye salmon stocks in Asia. The water volume is 14.6 km³, area is 79.25 km², and max depth is 316 m (Ponomarev et al., 1986). A river

connects it to the Sea of Okhotsk. Level fluctuations' range is 1.3 m. Mineralization is 69 mg/l. The lake is a nature reserve and a nature monument.

The Kamchatka's largest lake Nerpichye is of *lagoon type*, connected to the Kamchatka Bay, Pacific Ocean. The lake abounds in fish, a special land-locked form of herring lives there. Lake Kronotskoye is the largest freshwater lake on Kamchatka, located within the Kronotsky nature reserve, 30 km north of the world-famed geyser valley. It is of volcanic origin, formed when volcanic lava dammed a river valley. The level fluctuations' range is several tens of centimeters. It is ice covered from late December to mid-May.

Islands in the Pacific and Arctic Oceans contain about 40,000 lakes with a total area of 3,517 km² (Domanicky et al., 1971).

Russia contains lakes listed as UNESCO World Natural Heritage – Baikal and Teletskoye – as well as drainage basin of Lake Ubsu-Nur, and Lake Kurilskoye is a nature reserve and a nature monument within the “Volcanoes of Kamchatka.” Besides, Lake Chany and its catchment are in the UNESCO list of wetlands of international importance.

Lakes of the East European Plain (Russian part)

The East European Plain is one of the largest plains in the world, with an area greater than four million square kilometers (Figure 1). Most of it is part of the Russian Federation. Nearly all of the Russian portion settles along the Precambrian plate. The latitudinal-zone landscape differentiation from tundra up to steppe is pronounced. The landscapes change from weak to typically continental by longitude.

During the last million years, the so-called Quaternary Period, the East European Plain was covered by continental glaciers no less than four times. The most ancient glaciations, "Okskoe," occurred about 500,000–600,000 years ago and reached the River Oka basin above the confluence of the Oka and the Volga. Later, about 200,000 years ago, the maximal glaciation "Dneprovskoe" followed. At this time the heavy ice sheet was distributed to the south of Kiev, Kharkiv, and Voronezh; its two glacier tongues reached the south along the valleys of the Rivers Dnepr and Don. The subsequent "Moscow" glaciation took place about 150,000 years ago and reached the latitude of Moscow. And more recently in geological chronology, about 80,000–12,000 years ago, the glacier that reached only up to Valdai covered the northern part of the Russian Plain; consequently, this glaciation is named "Valdaiskoe." The Valdaiskiy ice sheet covered Scandinavia, Finland, a hollow of Baltic Sea, and adjoining areas of Northern Europe with a heavy cover. Its thickness in the center, in the Scandinavian mountains, reached 2,500 m, and on the borders about 500–700 m. The result of this glacial activity in the northern part of the East European Plain is the prevalence of glacial and water-glacial forms of relief.

The East European Plain can be divided into three parts by the peculiarities of lake hollow formation: Karelia, the

northwest of East European Plain, and the center and the south of East European Plain.

At Karelia there are many lakes (they cover about 11% of the territory). It underwent active plowing during the advance of the last glaciation. Over thousands of years, the heavy ice sheet, reaching a height of more than 1,500 m, was situated there. At the time of glacier contraction, violent streams of thawed snow flowed through the hollows formed at its bed. As a result, the formation of lake hollows of a glacial-tectonic or glacial origin took place here. Today in Karelia there are about 60,000 lakes, including the largest lakes in Europe – Ladoga and Onego. Moreover, Lakes Vygozero, Topozero, Segozero, Pjaozero, Vodlozero, Kuito, Sjamozero, Paljezero, and Tikshozero are of considerable size. The total area of all the lakes of Karelia makes up nearly 40,000 km². At the same time, more than 97% of the lakes have a water surface less than 1 km², and their general total area makes up about 10,000 km². Many lakes (about 75%) are located in the northern part of Karelia, between 63 and 66°30'N. The lakes of Karelia belong to the White and Baltic Sea basins. All large and middle and the majority of small lakes have the outflow; this is favorable to the breeding of fish and other organisms. Connected by rivers, the lakes form a complex system with naturally regulated drainage. Annual fluctuations in the levels of the majority of the lakes average about 0.5 m.

The lakes frequently consist of one narrow, long stretch and many narrow lips and gulfs. Theirs characteristic feature is numerous islands. A relief of the bottom is extremely irregular; areas of great depth are frequently stretched as the narrow trenches alternate with underwater rises or banks. Quite often, coastal heights ("selgi") approaching the lake continue under water. Depths change from 10 up to 100 m and more, however, maximal depth on average equals 20 m. The significant depths are favorable for the distribution of kryophila fishes: grayling, trout, and whitefish.

In deep Karelian lakes the temperature of the water in benthonic layers in the summer reaches about 7–10°C, at the depth of 10–15 m the temperature increase from 12°C up to 17°C, and the surface layers warm up to 19–23°C. These are typical lakes of a temperate zone, with the return temperature stratification during the winter period and direct stratification in the warm part of the year. The ice regime, regardless of meteorological factors, depends on the area of water surface, depth, and volume of lakes. With the approach of winter the small lakes and gulfs of the big lakes become covered with ice, and the coastal parts of the big lakes follow. Finally, the central parts of the big reservoirs freeze. The majority of lakes freeze from the end of autumn or beginning of winter until April or May.

Practically all Karelian lakes are fresh, with very weak mineralization of waters (10–20 mg/l) and low conductivity (5–8 µS). Slightly greater mineralization is characteristic of Zaonezhie (from 30 mg/l). In the lakes the hydrocarbonates usually dominate among the ions, and

Russian Lakes, Geographical Classification, Figure 1 Physico-geographical regionalization of Russia (According to Isachenko and Shlyapnikov 1979).

seasonal variability of mineralization structure is small. Oxygen conditions are favorable for the majority of lakes. pH ranges from 6 to 8; only in acidic lakes is it lower: 5–6. The organic substance is generally indigenous and rich in nitrogen. Intensity of the development of primary production and biomass usually is not high.

Oligotrophic lakes are typical for Karelia. The majority of them are situated in the north of Karelia, in northern Priladozhie (Varpajarvi, Salmentakaynen); slightly fewer at the Onego-Ladoga watershed (Lizhmenskoe, Topornoe, Suvyajarvi) and Shuisko-Sunskiy watershed. Many small Karelian lakes belong to a class of mesotrophic lakes; most are situated in northern Priladozhie (Lakes Pjuhjarvi, Kotjarvi, Yaimajarvi), at the Shuisko-Sunskiy watershed (Sjapchezzero, Mjaranduksa) and Onego-Ladoga watershed (Njalmozzero, Nikonovo). Eutrophic lakes are rare; they are found at the Onego-Ladoga watershed (Hlebnoe, Pelteri, Kaskozero) and Shuisko-Sunskiy watershed (Vuozhozzero, Vohtozero, Naidemozero, Peldo). Often their location is connected to a cultural landscape, but for some lakes the trophic level is caused by very shallow depths or by other reasons of natural character. In Karelia

there are many acidic (acidotrophic) lakes, found at the Onego-Ladoga watershed and also in the Veshkelitskaja group of lakes and near Konchezzero. They are short-drainage lakes with surface areas from 2 up to 100 ha, but in some lakes it is greater. The average depths change from 2 up to 9 m, maximal is from 4 up to 24 m. The characteristic feature of acidic lakes is an acid reaction of water (pH less than 6) in combination with the small values of permanganate oxidizability (usually below 6 mg O/l). At the Onego-Ladoga watershed there are dystrophic lakes, too, the largest of them having surface areas not exceeding 50 ha.

The northwest of the East European Plain includes most of the northwestern region and the northern region of Russia. The southern border passes through the Valdai Hills and coincides with the southern border of distribution of the last glaciation. In this part of the East European Plain there are many lakes also, but not more than in Karelia (they cover from 1% to 3% of the territory). Most lake hollows are formed in the depressions of moraine relief that remained after the glacier contraction. The height of the moraine here reaches from 60 to 80 up

to several hundred meters (Luzhskaja, Sudomskaja, Bezhanitskaja Heights, etc.). The formation of lakes is connected with thawing of buried ice blocks or with destruction of enormous ice fields. Some lakes occupy the bottoms of former river valleys filled with fissured ice or the narrows formed by thawed glacial waters. Such lakes are usually strongly elongated. They are shallow with average depths up to 3 m, maximally 6–8 m (Lakes Jazno, Dolysskoe, Rudo). Extensive glacial lakes were formed on the flat plains near the edge of a glacier. In the process of glacier contraction they were drained, and the flat lake plains were formed in their place. Today there are many lakes here. Lakes Pskovsko-Chudskoe, Ilmen, Beloe (White), Kubenskoe, Vozhe, Lache, Kenozero, Kozhozero, Undozero, and Lekshmozero are the largest postglacial lakes, with areas surpassing 100 km². Average-size lakes include Zhizhitskoe, Dvin-Veliskoe, Polisto, Sebezhscoe, Nevelskoe, Necheritsa, the Bolshoy Ivan, Ale (Pskovskaja oblast), Vyshtynetskoe (Kaliningradskaja oblast), Kolgachihinskoe, Chelozero, Pelozero, Sharozero, Syvtzero, Kovozero, Krasnyi Okun (Red Perch), Sojalskoe and B. Pinezhskoe (Arkhangelskaja oblast), Samro, Vrevo, Cheremenetskoe, Vjalie, Stregno, and Sjaberskoe (Leningradskaja oblast).

The floodplain lakes located along the majority of the large rivers also have a wide distribution in this region. Interesting examples are the Kuilokskie salty lakes, which are located not far from the River Pinega and are used for salt extraction. Their origin was connected to chemical and mechanical destruction of saliferous breeds located there. In places where soluble rocks, such as limestones and dolomite, lie close to a surface, the karstic lakes are distributed. They are situated at Belomorsko-Kuloiskoe Plateau, at Onego-Dvina watershed, and also in the area of Megorskaja Ridge (east of Leningradskaja oblast). Karstic lakes periodically disappear. Lake Koigushskoe (Megorskaja Ridge) is a typical example of these lakes. Some karstic lakes are intensively overgrown and become bogs. On the coast of Finland Bay there are some lagoon lakes with salty water (for example, Lake Gorvaldajskoe formed due to a branch from Finland Bay by a narrow strip of sandy dunes).

In total, in the northwest there are about 30,000 lakes of glacial (moraine), and, also, river and karst origin. The majority of lakes belong to the Baltic and White Sea basins, and to the lakes of Upper Volga (basin of the Caspian Sea).

The number of oligotrophic lakes at the north and northwest of the East European Plain is a small. They are confined mainly to the north (Arkhangelskaja oblast) of this territory. Mesatrophic and eutrophic lakes prevail. The majority of lakes are in “a stage of ageing” – the hollows of many deep-water lakes are characterized by significant accumulation of mineral and organic deposits overlapping the fine roughnesses of the bottom. Their coasts are flatter, the depths accrue gradually, and the shoals are typical. The zones of emerged (aero-aquatic), floating, and submerged macrophytes are strongly

pronounced near the coast. The active development of phytoplankton is observed. The transparency of water is low, up to several meters. The largest lakes of this type are Pskovsko-Chudskoe, Ilmen, Zhizhitskoe, Sebezhscoe, and Bolshoy Ivan.

The hydrological regime of the lakes is characterized by small changes in water level. Significant changes in level are observed in the majority of karstic lakes. The striking exception is Lake Ilmen, the level of which can change by 7 m. The temperature regime of lakes is substantially determined by the depth of a reservoir and its susceptibility to wind activity. The majority of deep lakes are characterized by the formation of direct stratification during the summer, return stratification during winter, and two periods of homothermy (spring and autumn). However, the formation of clear thermocline and significant divergences between superficial and bottom temperatures are observed only in the few deepest lakes. The water in shoals usually mixes up almost completely. The summer surface temperature is usually 18–20°C, and for shallow lakes is 24–26°C. The formation of an ice cover on the majority of lakes occurs in November–December, and an ice break in March–May (depending on latitude and lake size). On some reservoirs the ice-field is not formed annually (the lakes of Vishtvenetskaja Height). The mineralization of water is usually not high, up to 100–150 mg/l, and conductivity is 6–30 µS. Excessive mineralization (to 400 mg/l) is observed in lakes of Bezhanitskaja Height and in some lakes of the Arkhangelskaja oblast. The accumulation at the bottom of a large mass of sapropel is typical for many lakes of the northwestern part of the East European Plain. Sapropel is extremely valuable and is widely used in the economy.

The center and south of the East European Plain includes the Central and Central–Chernozem regions of Russia and the Middle Volga region. In this territory there are the fewest number of lakes that have been subjected to the last glaciation. However, the previous glaciations (Moscow, Dneprovskoe) left a trace in the formation of its relief and took part in creation of some lake hollows. In the center and the south of the East European Plain there are some 1,000 lakes. Most are small in size; only a few surpass an area of 10 km²: Lakes Plestcheevo and Nero (Yaroslavskaja Oblast), Galichskoe and Chuhlomskoe (Kostromskaja Oblast), Asylkool and Kandrykool (Bashkortostan), Velikoe and Svjatoe (Mestchera), and a few others. These lakes belong to the basins of Black and Caspian Sea.

The floodplain and karstic lakes prevail in this region. Lakes Plestcheevo, Nero, Gavrilovskoe, Sapsho, Chistik, Baklan (Cormorant), and Rytoe are the rare examples of glacial lakes. Among floodplain lakes there are many meander (oxbow) lakes; their form is lengthened or horseshoe-shaped, preserving the bends of a river channel. Such lakes are widely distributed in the Volga region and in the flood plain of the Rivers Kama, Oka, and Desna. Karstic lakes are typical in most of the center

and south of the East European Plain; many of them are situated in the Volgo-Vjatskiy region, Bashkiria, and Penzinskaya Oblast. Karstic lakes have significant depth and an oval form. Often they are closed water bodies without a superficial drain and even inflow, and their surface area is insignificant. Many lakes are extraordinarily clean and highly transparent. Their mineralization varies and is usually determined by the character of the underground water connected to lake. Water of deep karstic lakes usually is low in temperature, remaining cold even in the summer. Another feature is their low ability to freeze. The largest karstic lakes are Asykkool and Kendrykool (Bashkortostan), with surface areas of 23.5 and 15.6 km², respectively.

The hydrological regime is determined by the origin of the lakes. Many lakes have rain, snow, and underground feeds. Karstic lakes are mostly characterized by the presence of underground feed. The feed predetermines the mineralization of lakes. On average it is about 100–200 mg/l and the conductivity is 18–60 µS; in karstic lakes the mineralization may be greater, from 1 g/l up to 12 g/l.

Lakes of the Kola Peninsula

The Kola Peninsula is in the far northwest of the European part of Russia in the northeast outlying districts of the Baltic Shield. The peninsula geological formation consists mainly of Precambrian and Paleozoic crystalline rocks and its relief and low evaporation are favorable for many lakes. And indeed there are some 110,000 lakes in the Kola Peninsula. The largest lakes have a glacial-tectonic origin and, during the Quaternary glacial period, lake basins were substantially reformed and sculpted by glacial erosive activity. Most of the lakes are characterized by low water temperatures, long periods of ice cover, cleanliness, high transparency conditions up to 11 m, low mineralization, and low organic substances. Almost all lakes are oligotrophic.

The largest lake is Imandra, with a surface area of 812 km², maximum depth 67 m, and a 127 m elevation. Many rivers enter the lake, including the Pirenga and Moncha, forming a complex river-lake system. The largest outflow river is the Niva. There are more than 140 islands, the largest being Erm Island of 26 km² in area. The lake feed is mainly by snow and rain water; lake cover is observed from December until May. There is an abundance of fish, including whitefish, grayling, and loach. The deepest lake in the Kola Peninsula is Lake Umbozero, with a maximum depth of 115 m. Other large lakes include Lovozero, Notozero, Kovdozero, Kolvockoe, Kanozero, Vyalozero, Segozero, Ondomozero, Enozero, Babozero, Lyavozero and Kolozero.

Practically all small lakes in the Kola Peninsula have had little limnological investigation and only a few in the stony tundra on the coast of the Barents Sea, such as Lakes Zeleneckoe, Akulkino, and Pozdnyakovskoe, have been ecologically investigated. The ice cover extends for at least 8 months. The oxygen content in the water is high,

with a pH of 6.5–7, and transparency is also high at 4–5 m. A homothermal period after ice break is usually not maintained for a long time, however, the difference in temperature between the surface and bottom layers does not exceed 4°. The lake water has low mineralization, the dominant ions being Cl[−] and HCO₃².

The amount of organic substances is small and substantially stable, and there is an insignificant amount of iron or biogenic elements. The *fauna* dominating in cold waters is of palearctic and holartic forms, and there are the glacial *relicts*.

The following lakes have been investigated in forest tundra and the north *tayga* zone: Lakes Konentyarv-Kolgiyarv, Polyarnoe, Berezovoe, Vyalozero, Senozero, Pasmozero, and Velikom. In many of these lakes banks are formed by boulders, shingle, and gravel as well as sandy deposits. Bottom sediments have low content of organic substance and a prevailing component of their structure is authigenic silica diatom in the phytoplankton. The intensity of photosynthesis is low and absorption of oxygen intensive, resulting in a negative daily balance of organic substance. In the lakes of the forest tundra, mineralization is low and the water is of chloride–sodium type. Lakes are subject to strong winds and oxygen saturation is high. The structure of phytoplankton is varied, about half belonging to a type Chlorophyta.

Biomass is not more than 0.2 g/m³ and photosynthesis is 0.3 mg O/l day

In lakes having higher organic substance in bottom sediments, the *zoobenthos* is richer and *Chironomidae* is the dominant family.

The ecological status of the lakes of the Kola Peninsula is good, although problems with dumping of large quantities of waste, some polluted, has been experienced, mainly from industries and the cities of Monchegorsk, Zapolyarnyi, Nickel, and Murmansk.

Lakes of Bolshezemelskaja and Malozemelskaja Tundra

The North-Pechora tundra province is situated at the northern part of the Pechora Lowland, to the north of the Polar Circle. This territory is a wavy plain with numerous heights and ridges. The Malozemelskaja tundra is situated between the Rivers Timan and Pechora. It is a monotonous, marshy, and lacustrine lowland with separate frontal moraine ridges. The Bolshezemelskaja tundra is situated to the east of the River Pechora; it is an extensive lowland occupied with bogs and lakes.

The surface of tundra abounds in numerous small lakes whose origin was in thermokarst processes. Thermokarst lakes are subject to periodic disappearance and to reoccurrence. There are also lagoon lakes, generally small in size, with lengths under 2 km and depths about 3–4 m. The lakes are located among bogs and have peat or swale coasts. Larger lakes are found in areas of glacial sediments. Among the largest lakes are Golodnaja Guba (Hungry Lip), Pilnja, Vashutkiny, Vatiarty, Urdjuzhskoe, Bolshoe, Tainto, and Oshkaty.

The lakes of Bolshezemelskaja and Malozemelskaja Tundra are situated in a cold continental climate. These are oligotrophic lakes with ice cover for most of the year and low water temperatures in summer. Bathymetric surveys and water quality investigations have been carried out on the Prosunduiskie lakes, the lakes of Harbeiskaja System, and the Pilnenskaja group of lakes. The largest lake of the Pilnenskaja group is Pilnja, with a surface area of 51.6 km², average depth 1.4 m, and volume 0 km³. The transparency is only 1 m. Green and diatom algae are the predominant forms of phytoplankton. Fish life includes whitefish, grayling, northern nine-spine smelt, and several types of salmon.

In Nenets in the east of the Bolshezemelskaja Tundra, the Harbeiskaja system includes three connected lakes: Golovka, Bolshoi, and Maly Harbey, which are surrounded by shallow lakes. The system includes the River Sayda of the River Usa system. The catchment is marshy. The lake coastlines are varied, with many bays, and there are numerous islands. All lakes are free from ice cover during the short period of from July to September. Lakes are homothermal as a result of wind mixing. The lake water has a low mineralization and contains biogenic elements of phosphorous and ammonia, but nitrites and nitrates are almost absent. Organic substances in the lake water have an allochthonous origin. The photoplankton complex includes widespread boreal and subalpine species. Ichthyofauna is of the arctic freshwater kind.

The Prosunduiskaja lake system has 29 lakes with a total area of 26.4 km². Most lake basins show evidence of relief and low banks. The duration of the frost-free periods averages 70–80 days and the lakes are opened in the middle of June. The Prosunduiskie lakes belong to a class of small water bodies of area from 10 to 535 ha. The greatest depth does not exceed 13 m. Bottom sediments are mainly of a sandy nature and most lakes have a sandbank form of shoreline of about 1.5–2.0 m. The stratification is observed in summer on deep-water sites of lakes. During the open water period the content of dissolved oxygen is high and nearly fully saturated, mainly as a result of intensive wind mixing. The lake water is poor in biogenic elements and investigation shows that there is carbonic acid present. Ichthyofauna is represented by white salmon, whitefish, ide, and migrating forms. Some species continue to live in the lakes.

Lakes of the North Caucasus and Pre-Caucasus

The Caucasus Mountain country belongs to the Alpine folded zone. There is a considerable variety of landscape, from pluvial variations of deciduous and Mediterranean types to sub-boreal Steppe, semi-desert, and subtropical desert with belts of herbaceous Alpine glaciers. In the North Caucasus there are more than 1,000 lakes, most of them being confined to middle and high altitudes. The lakes are of glacial, collapse, or karstic origin, although lakes are also found in the foothills.

The largest lake of the foothills of Krasnodar Kray is Lake Abrau. The lake is fresh water, 2.5 km in length, maximum width is 600 m, and surface area is 1.6 km². It is believed that the lake was formed as a result of karstic collapse or that it is a remainder of an ancient Cimmerian freshwater basin. There is also a version that connects its origin with an enormous landslide. Another large foothills lake is Lake Samurskoe, with a surface area of 0.46 km².

Estuaries and lagoons are widespread along the Black Sea and Azov coasts, and are also found between the mouths of the Don and Kuban Rivers. There are about 250 water bodies here, including both fresh and saline lakes of the Kuban River Delta. The largest of these is the Eiskiy estuary, whose surface area is 244 km², although there is also the large group of Beysugskies and Abtarskies estuaries with considerable area. Among the Kuban Delta lakes, the large freshwater lakes include Ahtanisovskiy (336 km²), Vityazevskiy (55 km²), and Kyzyltashskiy (142 km²). All of them are shallow.

The picturesque lakes of the middle and high altitude of the Caucasus have lead to worldwide interest in the area. However, the difficulty of access has had an adverse effect on their investigation. The lakes have high transparency and are noted for the blue or sea-green color of their waters. They are divisible by their origin to damming and landslide lakes, glacial and moraine, and karstic and tectonic.

Natural damming of lakes was a result of collapse and landslides damming up the valleys of mountain rivers with natural barriers and weirs. Landslide lakes are found in the catchments of Chanty-Argunskiy and Shero-Argunskiy watersheds and in the Shikoroy. A typical lake is the high altitude Lake Kezenoiam situated at an elevation of 1,860 m at Andiyskiy Range near the border of the Chechen Republic and Dagestan. The lake was formed by a landslip that dammed the valleys of the River Horsuma and the River Kauha. The lake has steep slopes and a flat bed. The natural dam is 100 m high. The surface area of the lake is 2 km and depth 72 m.

Another lake of the dammed type is Lake Mochoh (Dagestan) situated at an elevation of 1,600 m at the River Mochohtau Andiyskiy basin. The lake was formed by the Mochohskiy landslide in 1963. Its length is 1.3 km, width is 300–400 m, and the depth ranges from 20 to 30 m with a maximum of 60 m.

The following lakes were formed by landslides, avalanches, or earthquakes: Lake Achipsta (surface area 60,000 ha), situated in the Caucasus Biosphere Reserve, formed as the result of a huge avalanche over the Achipsta River. Lake Inpsy (surface area 7.5 ha) formed during an earthquake as a result of a landslip that dammed up the River Tzahvoa and others. The following are examples of tectonic lakes: Lake Hyrtana situated on the Main Caucasus Range near the border of Dagestan and Azerbaijan. The lake is situated at an elevation of 3,210 m and is the highest lake in the North Caucasus. Lake Galanchozhskoe, situated at an elevation of

1,533 m in the River Osu-hi valley, length 450 m, width 380 m, and depth at the center 31 m. There are many widespread deep karst lakes in North Caucasus, the best known of which are Lake Cerikkel at Kabardino-Balkaria, with a depth of 368 m, and Lakes Pahurov and Sherek-Yana, with depths of over 200 m.

Mountain lakes of North Caucasus are overflow and closed basin. Depending on groundwater flow, lakes vary in salt content, although most have a good supply of fresh water. Depths are considerable, especially in karstic and tectonic lakes. High altitude lakes have low temperatures even in summer and suffer a long freezing period. For example, Lake Kardyvach (upper course of the Mzymta River) is closed by ice almost all year. Ice floes are present even in summer. Almost all lakes are oligotrophic and poor in organic content. They are fed by snow, rain, and groundwater in many cases. If feeding is deficient some lakes become shallow in summer (for example, Lake Achipsta).

Many lakes in North Caucasus have a short life; some disappear, especially during the washout of dams. For example, Lake Dultychayskoe emerged in 1905 and vanished in 1958. Other lakes slowly drain away into rocks and dry up or flow into swamps.

At the same time, however, tectonic and mudflow activity set up the formation of new lakes. The principal features of the mountain lakes of the Caucasus are their aesthetic value and their preservation of a pristine environment due to their remoteness.

Lakes of the Caspian Lowland

The Caspian Lowland is part of the Turanskaya Plain – the lower lands with accumulative and arid-denudation relief on the epihercynian platform. The northwest part of the Caspian Lowland belongs to Russia. The climate is arid. The lakes, about a thousand of them, are generally saucer-shaped depressions. The origin of lakes is tectonic or damming. Depending on their location some lakes are somewhat saline with various concentrations of salinity. Many of the lakes are temporal, with water infill during spring snowmelt only, they contain fresh (melting) water. Stretching south of Volgograd over the Kalmykia Steppe there are the Sarpinskies lakes including Lakes Sarpa, Teatca, Barmantcak, Prishib, Hanata, Kanurka, Deed Hulsun, Buzga, and others. These shallow lakes dry up in summer and, because of the ingress of sewage, their quality is generally low.

Within the Volga-Ahtubinskaya flood lands and the At Volga Delta there are the “ilmens” or the “poloy.” These lakes are concentrated in the west of the Volga Delta and their origin is connected with wind activity and the contraction of the Caspian Sea. The contraction of the Caspian Sea has had the effect that the water in the lakes has filled the deeper parts only. The lengths of these lakes vary from hundreds of meters to some kilometers and widths within the range 150–1,000 m and depths from 0.5–3.5 m, the largest being Lake Bolshoi Beshkull, 10 km in length. At the edge of the Volga Delta the “kultuks” lakes owe their

origin to their separation from the sea by sandy sediments, spits, or banks. The Kultuks are shallow (0.5–1 m) and with warm summer water they are covered by white water lilies, water chestnuts, and reeds.

Some lakes maintain water all year and are substantially fresh, but the majority of lakes are salty. Salt extraction of saline lakes continued to the twentieth century. The well-known Malinovoe (Crimson) Lake of Empress Ekaterina was noted for its elegant rose-crimson color due to the microorganisms (*Seracia sallinaria*). The best known salt lakes are Lakes Baskunchak and Elton. Lake Baskunchak has a surface area of 106 km² and elevation 21.3 m. It is a tectonic lake compensated by salt strata formation. The depth of salt surface deposits is up to 4 m and as much as 18 m near the coast. Surface brine, up to 0.8 m in depth, appears in winter and spring. The spring feed to the lake amounts to 24 million liters and 2.5 thousand tons of salt per day. Accumulation of salt amounts to up to 50 m and deposits of salt up to 10 km in the earth's interior were discovered under the lake. Lake Baskunchak is part of the Bogdansk-Baskunchakskiy Nature Complex, declared as a natural reserve in order to preserve the original flora and fauna.

Lakes of the Ural

The Ural-Novozemelskaya Mountain Country is a Hercinian folded construction that has been the subject of thousands of years of denudation and of more recent creation of low and average mountains in a meridional direction from the Arctic to the semideserts. In Northern, Middle, and Southern Ural there are more than 10,000 lakes.

In *North Ural*, including Polar, Subpolar, and Northern Ural, there are some 4,300 lakes with a total surface area of about 200 km². The numbers of lakes notably decreases from north to south, in the Polar Ural there are about 3,300 lakes, in the Subpolar Ural there are 820 lakes, and in the Northern Ural about 212 lakes. On the humid western slope there are more lakes (about 2,700) than on the eastern (about 1,600) one. Generally these lakes are small water bodies with areas of about 1–2 km². Only Lakes Big and Small Stchutchie have surface areas of 12 and 4 km², respectively, which are the largest in the Polar Ural having glacial and tectonic origin. The largest lake in the Subpolar Ural by area and volume is Lake Torgovoe (Trading) in Keftalyk, dammed by a moraine, having a length of 2.2 km and width of 0.8 km, surface area 1 km² and depth of 28 m; it is the deepest dammed lake in the Ural. The bottom of the lake is transparent to a depth of 8 m and rich in grayling. Other deep lakes are Lake Muncie of Subpolar Ural (38 m) and Lake Telpos of Northern Ural, surface area 0.25 km², elevation 1,081 m, and depth 49.5 m.

In general, the lakes in the North Ural have a glacial origin in deep corries and cirques. Corries lakes differ by their high elevation (above 800 m) with large depths (up to 20 m) with rounded form on a stony coast almost devoid of vegetation and frequently an absence of fish. In the

valleys there are numerous lakes formed by damming the rivers by moraine: Big and Small Balbaty, Torgovoe (Trading), Dlinnoe (Long) with depths of up to 30 m with an elevation as low as 800 m or even lower. These lakes are rich in fish life, with forest and shrub widespread on the coasts. There are many lakes adjoining the mountains of Northern Ural in the Western-Siberian and Pechora Lowlands. They are located to the east of the Ural Ridge in Lozva, Northern Sosva, Lyapin, Voykara, and Stchutchja (Pike) Basins. To the west of the Ural Ridge, there are not as many lakes, and they are concentrated mainly in valleys and flood-lands of the Rivers Usa and Kara and their inflows. The lowland lakes have areas up to 5 km² and are not very deep (up to 7 m). Thermokarst lakes are distributed along the Ural sides of the Western Siberian and Pechora Lowlands but in the mountains they are rare, especially in the Polar Ural but they occur in the Lake Small Hadata-Ugan Lor basin and in the Big and Small Kary valleys.

Middle Ural is the least raised part of the Ural Mountains and the most populated and industrially active area, with many small lakes, on the order of surface areas 1 km², and of glacial-tectonic origin. The depths of these lakes are small, on the order of 3–5 m. Many lakes of Middle Ural are essentially modified in connection with economic activities in this region.

The following lakes are the largest in the Middle Ural: Lake Tavatuy with an area of 21.2 km², a drainage area of 104 km², a maximum depth of 9 m with outflow River Neiva; Isetskoe Reservoir with an area of 24 km², a drainage area of 600 km²; Lake Shartash with an area of 6.9 km², a drainage area of 41 km², and a depth of 4 m. The water level of Lake Shartash has decreased over the years, and at the beginning of the nineteenth century this depression of the water level was believed to have been due to the construction of branch ducts to supply water to the gold mines. The lake ceased to dry up in 1920. It is now one of the best commercial fishing lakes in the Ural, especially for carp. Because of the lake's shallowness, the lake temperature rises in summer to the extent that the temperature on warm summer days reaches 30°.

The Southern Ural is rich in lakes; in Chelyabinskaja Oblast there are some 3,170 lakes with a total surface area of 2,125 km². Small lakes with the area less than 0.5 km² (about 80% from general number) prevail, though some 100 lakes have the areas greater than 5 km². The lakes stretch in a strip from the Chebarkulskaja Lake group in the south up to Sinarskaja in the north. The largest lakes are Lake Wildy (area 68.1 km²); Lake Turgojak (area 26.4 km², maximum depth 34 m); Lake Yaktykool (area 7.7 km², depth 28 m); Lake Talkas (area 3.9 km², maximum depth 12 m); Lake Irtyash, Lake B. Kisegach, and Lake Kaslinskije. They are the tectonic lakes with great depth, up to 30–40 m.

There are many lakes in the forest-steppe zone of Zauralye. They mainly consist of large water bodies including Welgi, Shablisch, Argajash, B. Kujash, Kaldy, Sugojak, and Tioshki, all of them having their origin as

erosive-tectonic type. The depths of these lakes do not exceed 8–10 m. The karst and flood-land lakes have significant spread also. Karstic lakes usually have small sizes and significant depths (up to 10–15 m and more), but flood-lands are shallow.

The lakes of the Southern Ural are productive. Fish life is rich but it has been disturbed by fish-kills. Nevertheless, there are numerous catfish, carp, pike and perch, bream, and whitefish. More favorable conditions for ichthyofauna are in the lakes of the foothill areas characterized by a stable hydrological regime. Lakes of the Southern Ural are rich in various balneological resources, too (organic and mineral mud, alkaline waters).

The lakes of the West Siberian plain

The West Siberian Plain has an area of some three million square kilometers. It is mainly low-lying and of a boggy nature with an accumulative relief, occupying a part of the Epi-Hercynian platform with large thickness of Mesozoic-Cenozoic sediments.

The climate is typical continental with zones of tundra, a taiga, pretaiga, and forest-steppes or steppes. The area is one of the richest in lakes in Russia, especially in the north. In the Yamal-Nenets district alone there are about 300,000 lakes and in the district of Hunts- Mansiyskiy there are from 200,000 up to 300,000 depending on different estimates. Almost all the lakes are shallow, with areas less than 1 km². In the south of West Siberia, in a steppe and forest-steppe zone, although lakes there are less dense, there are some 10,000, some of which are salt water lakes.

Lakes are of various types, but thermokarst lakes prevail. They are located in tundra, in a zone of permafrost. Most of these lakes are small and of shallow depth. Shallow lakes freeze to the bottom during the harsh Siberian winter and in larger lakes the ice is generally 2 m thick. In the spring in the tundra lowlands, more than half are covered with water; by autumn in some regions the area of the lakes is reduced and some disappear, of which those on the Tazovskiy and Gydanskiy Peninsula are good examples. Along with the small lakes in the Tundra there are some large lakes, for example, Lake Neito (surface area 250 km² and depth 4 m), Lake Jaratto (surface area 150 km² and depth 8 m), and the lakes Jambugo, Jambuto Jaroto, and Hosato.

To the south in the Taiga zone, there are many lakes or "staritsa" (former river bed) in the wide flood plains of the Rivers Ob, Vasugan, Vakh, and others. These water bodies are small, with elongate, arcuate, or falcate forms. In the flood plains of some rivers to the east of the Urals there are lakes or "sory" with surface areas as large as tens of square kilometers, including Vorchato, Voikarskiy Sor, Vanktto, and Big and Small Halce-Lor. Lakes – "Sory" – are located in low lands and in rivers valleys; they have flat hollows and an oozy, fenny bottom; depths are mainly from 1 up to 3 m. Sory fill during spring floods; by the end of summer the water level falls and sory turn to boggy lowlands. The largest lakes of the Taiga zone, with areas exceeding 30 km² include

Shuryshkaraskiy sor, Kondinskiy sor, Big and Small Soviet, Makovskoe and Nalimie, Nunto, Pjakuto, Chaselskoe, Chertovo, Tormentor, Vandmtor, Untor, The Big Sor, Syrkovoe, Tursunskiy Tuman, Leushinskiy Tuman and Pelymskiy Tuman, Jahtur, and Temrjak.

There are an abundance of lakes of various sizes in steppe and forest-steppe areas whose formation is related to relief features and water balance. In conditions of flat relief and large losses to evaporation the majority of lake basins are endorheic. Melted snow waters play the main role in feeding the lakes. At the same time, ground water has essential value, especially for large lakes. The number of lakes is estimated in thousands, probably more than 11,000 in Altai alone. It is convenient to summarize the following main groups:

1. The lakes of Kulundinskaja steppe include the largest salt-pan Lake Kulundinskoe, surface area (728 km²), Lake Kuchukskoe (181 km²), Bolshoe Topolnoe (Big Poplar) (77 km²), and Bolshoe Jarovoe (Big Spring) (68 km²).
2. The lakes of Ishimskaja steppe include a number of small reservoirs between the Rivers Irtysh and Ishim, the largest being Lake Bolshoy Uvat, Kartabyz, and Malyi Donki.
3. The lakes of Zauralye include many shallow steppe reservoirs of the Chelyabinsk and Kurgan areas, Lakes Mamynkool, Welgi, Butash, Kartabyz, Malyi, and Donki.
4. Lakes of Priobskoe Plateau including Lake Gorkoe (Bitter), surface area 140 km².
5. Lakes of Barabinskaja steppe including Lakes Chany (surface area 1,900 km²), Ubinskoe, Sartlan, Tandova, and Urum.

Saucer-shaped hollows of lakes are flat and are poorly visible on the plain. Their sizes change extremely depending on season. Lakes are large in the spring and small in the summer; many lakes dry up at this time. Lakes water is characterized by high mineralization; some lakes are hypersalt. Their salinity can exceed 100 g/l. The largest salt lakes are Kulundinskie, Mihajlovskie, Petuhovskie, and Borovye. The Kulundinskie lakes produce some 350 million tons of table salt annually. The greatest in this group is Lake Kulundinskoe, with a surface area of 728 km². Lake Malinovoe has a crimson shade of water.

Studies since the seventeenth century have shown that some lakes in the south of the West Siberian Plain are in continuous drying with changes of outline and size. A typical example is Lake Chany, the largest lake in this region located between the Rivers Ob and Irtysh in Barabinskaja Lowland on the border of steppe and forest-steppe zones. Lake Chany has a complex configuration consisting of two parts. The first includes the Big Chany Lake, whose structure includes Yarkovskiy, Tagano-Kazantsevskiy, and Chinjaihinskiy Reaches and Lake Yarkool connected with Big Chany by two channels about 1 km in length with the flow into the Chinjaihinskiy Reach. The second part is the Small Chany Lake

connected with the Chinjaihinskiy Reach by Channel Kozhurla, about 7 km in length. The changes in water level of the lake have been recorded since 1899 as follows:

An increase in water level took place between 1900 and 1914 (rise of 2 m) and between 1937 and 1950 (rise of 2 m). A reduction in water level and surface water area took place between the periods 1914–1937 and 1950–1970. In 1972 the construction of dams through the group of islands Udinskiy Reach separated the above parts of the lake. This allowed the reduction of losses by evaporation and raised the water level in the east part of the lake by 0.5 m. At the same time, however, the Udinskiy Reach inflow started to dry up and within 6 years the water level went down 1.1 m, progressively drying up the Udinskiy Reach until today.

The water balance of Lake Chany depends on precipitation and evaporation. However, it is believed that global warming has already had an effect on the long-term regime and on its drying over the past 100 years. At the end of the nineteenth century the area of the lake was 3,170 km; by the end of the twentieth century it had decreased to 1,707 km. Reduction of the surface area resulted in a change in temperature and oxygen in its water mass. The anthropogenous influence on the lake has consequently resulted in a deterioration of the water quantity and quality. The drying up of Lake Chany, as well as other numerous lakes of the Barabinskaja Lowland, continues.

Lakes of the Altai-Sayan Mountains Country

The Altai-Sayan Mountain country includes the high ridges of Altai (4,506 m), Mongolian Altai (4,362 m), Western Sayan (2,930 m), East Sayan (3,491 m), Hangai (3,905 m), and deep tectonic depressions. This mountain country appeared on Paleozoic structure revived by new tectonic movements. It is located on the border of typical and sharply continental sectors of Asia, with landscapes characterized by great variety and contrasts. On Altai the present glaciation is considerably advanced. The Altai-Sayan mountain country is rich in lakes. There are more than 15,000 in total. About 6,700 are in Tuva, about 7,000 in Altai, and about 300 in Hakassja. In the Teletskoe Basin there are some 2,200 small lakes. The area of lakes in Altai amounts to 600 km² and in Tuva about 1,100 km². These lakes have tectonic, glacial, dammed piping, and karstic origin. The largest lakes in Altai are Teletskoe and Dzhulukol. Among the largest lakes of the Sayan Mountains are Lake Noyon-Holl, Tere-Holl, and Lake Todga (Azas). Small mountain lakes prevail both on Altai and in Sayan.

Lake Teletskoe is the largest lake in Altai-Sayan with details as follows:

- (a) Tectonic depression processed by glaciers and filled with water
- (b) The lake consists of two parts – the north part of length 28 km, and the south part of length 50 km
- (c) Elevation 473 m
- (d) Width 3.2 km

- (e) Surface area 230 m²
- (f) Volume 40 m³
- (g) Maximum depth 325 m (one of the deepest in Russia)
- (h) Seventy percent of inflow, River Chulyshman
- (i) Outflow – River Bija
- (j) Evaporation loss of the order of 2%
- (k) Water level fluctuation 4–5 m, minimum in March, maximum in June–July
- (l) Transparency 6–12 m
- (m) Mineral and organic substances 80 mg/l
- (n) pH 7.3–7.6
- (o) Ichthyofauna is represented by 13 species including *Hucho* spp., whitefish, grayling, pike, minnow, perch, and eel-pot.

Both on Altai and in the Sayan Mountains there are large numbers of small lakes whose origins are from glacial activity such as the cirque lakes and moraine dammed lakes. The latter are located in the glacial valleys; their depths range from 7 to 10 m but large lakes have depths of several tens of meters. Lake Taymenye in Altai has a depth of 68 m. Lake Toga is a large glacial lake in the Sayan Mountains with a length of 20 km, a width of 5 km, and a depth of 100 m. While another, Lake Nayon-Holt, is some 225 m deep. Among the other largest mountain lakes are Lakes Uzun Kool, Yerri Holt, and Hindiktig-Holt. Most of mountain lakes are covered by ice from the end of September until the end of May. The feed is from melting glaciers. Thawed water brings silt, resulting in the white color of some lakes. For example, a bucket of water from Lake Ak-Kemskoe and others usually has a 5 cm layer of viscous bluish glacial silt.

Some lakes in Altai-Sayan have also been formed by internal erosion of Karstic origin. The beautiful Lake Ajskoe, for example, located on an ancient terrace of the River Katun at an elevation of 280 m, was formed in Upper Quaternary 20,000–25,000 years ago. The lake has a surface area of 87,500 m² and a maximum depth of 20–25 m. Lake Ajskoe is a national protected body. A number of fresh and saline lakes were formed in the lowered parts of the Tuva Hollow. Lake Chagytay, a large and the deepest fresh water body, is located here, with a surface area of 28.5 m², an elevation of 1,003 m elevation, and a maximum depth of 19 m. The lake is rich in fish such as ide, pike, bream, and carp. A significant number of lakes is situated in the top part of Yenisei basin, in the so-called Minusinskaja Hollow. Here also there are lakes with high mineralization of waters.

Many of Sayan lakes, for example Tuva lakes Svatikovo, Hadyn, Dus-Holl, Cheder, By-Holl, Shara-Nur, and Lake Azas, are famous for medical purposes, for instance, medical mud. One of the largest of them is the highly mineralized Lake Shira in Hakassija. Approximately 380 million cubic meters of medical highly mineralized water is concentrated in this lake. Another interesting water body is the saline lake Tus. Originally it was estimated that the salt content of the lake amounted

to 250 g/l, similar, in fact, to the Dead Sea. In the twentieth century, salt was extracted from this lake. After desalination, which is now taking place, the salt content has decreased to 155 g/l.

The lakes of Eastern Siberia

Eastern Siberia includes the North Siberian Country, Northeast Siberia, and the Central Siberian Plateau. The climate is extremely continental, arctic, subarctic, and boreal and sharp permafrost is distributed in all regions. There are tundra, forest tundra, and taiga and north taiga landscapes.

The North Siberian Country includes the North Siberian Plain, Byrranga Mountains (1,146 m), and the Northern Achipelago. Northern Siberia is mainly mountainous folded structures with the highest mountains Verkhojanskiy (2,389 m), Santar-Hajata (2,959 m), and Cherskogo (3,147 m). The Central Siberian Plateau lies on the Precambrian Siberian Platform. Heavy lava masses lie in the northwest (Plateau Putorana 1,664 m). Eastern Siberia is the richest lake region in Russia. In total there are more than 1,300,000 reservoirs. In Yakutia there are some 700,000 lakes and another 300,000 in Krasnoyarskiy Kray.

In Northern Siberia there are some 100,000 lakes, mainly consisting of small lakes in Pripoljarnomorskaja Lowland and along the marginal seas of the Arctic Ocean. The numerous small lakes of Yano-Indigirskaja and Kolymskaja Lowlands occupy about 9% of the total area of these regions. They are better known by the local name “layd.” Other small but numerous lakes, known as “lyby,” are located on the deltic islands of the Rivers Lena, Yana, and Indigirka. The majority of the lakes have a thermokarst origin and suffer from the thawing of buried ice with significant distribution in the Pripoljarnomorskaja Lowland. As a rule, thermokarst lakes have an oval or round shape, and the lakes formed in a riverbed have a lengthened form. Almost all lakes are shallow, the depth seldom exceeding 4 m. More lakes are connected by channels. The lakes are covered with ice from October until June; many lakes freeze to the bottom, which results in fish killing.

The largest lake in Northern Siberia is Lake Taimyr. Lake Taimyr, located north of the polar circle in the center of the Taimyr Peninsula at the foot of Plateau Byrranga, has a surface area of 4,560 km². The lake is shallow, having an average depth of 2.8 m but with a maximum depth of 26 m. The River Upper Taimyra flows into the lake and the River Lower Taimyr flows out of the lake to the Karskoe Sea. The lake is ice free for only 3 months of the year and during the arctic winter the ice reaches 2 m in thickness. Generally, about 80% of all the lakes freeze to the bottom. Lake Taimyr is rich in fish life, whitefish, eel-pot, grayling, omul, and Siberian goby, and birds include swans, geese, ducks, rough-leg buzzards, falcons, and peregrines. The birds spend the winter in the warm countries, but return to the area annually.

The other largest lakes in Northern Siberia include Kungasalah, Portjagino, Labaz, Kokora, Pronchistcheva,

Ajaturkuna (Taimyr Peninsula); Kieng-Kuell, Sappja (North Siberian Plain); Bustah, Orotko, Solungah, Mogotoevo, Omuk-Kuell, Hantagay, Dolgoe (Yano-Indigirskaja Lowland); Ozhogino (Abyjskaja Lowland); Ilyrgytgyn, Bolshoe Morskoe, Nerpichie, Ruzhnikova, Abe and Ulahan-Abe (Kolyma Lowland). The above lakes in Northern Siberia are located in an extremely sparsely populated area and their water quality remains practically pristine.

Northeast Siberia is also rich in lakes, especially in Anadyrskaja Lowland, which are usually small in size and shallow in depth. They have small sizes and insignificant depths. Their origin is mainly connected with the processes of frosty erosion and glaciations, but there are floodplain and tectonic lakes, too. Among the best known lakes in this region are Lake Krasnoe, with a surface area of 660 km², Emanda, (Plateau Janskom), Labynakyr, Alysadah (Ojmjakonskoe Plateau), and Malyk (Nerskoe Plateau). Along the coasts of Chukchi and the Bering Sea are a large number of large lagoons, notably Lake Lavrentija one of the largest.

Another beautiful lake in this area is Lake Elgygytgyn in Chukotka in the Anadyrskoe Plateau. This lake is deep bowled, with an 18 km diameter, and has a dense ultramarine color and a huge depth of 467 m and, contrary to the laws of physics, warm water lies below the cold water layer. The lake is rich in fish, with five different kinds of salmon.

Thermokarst lakes are typically found in the *Mid-Siberian Plateau* where their origin is connected with permafrost, particularly in the Lena- Viljuiskaja Lowland where fossil are found (buried) in ice. Most of these lakes are widely spread across the region and have the characteristic round shape. The lakes are young, being formed over a short period of time on the order of tens of years but they often dry up and disappear. This is particularly observed in the Lena-Amginskiy catchment area. At the beginning of the twentieth century there were hundreds of dried up lakes here. Along with the lakes drying, numerous cases of repeated filling have been observed also. There are many such lakes that gradually vanish and then periodically fill with water. In addition to thermokarst lakes, there are floodplain, tectonic, and glacial-tectonic lakes.

One of the most interesting lake areas in this region is Plateau Putorana with 20,000 lakes, over 100 of them having surface areas exceeding 1 km² and 18 lakes with surface areas exceeding 50 km². The best known is Lake Hantaiskoe, having a surface area of 1,560 km² and a depth of 420 m, and Lake Pyasino with surface area of 735 km². The hollows of these largest lakes by their origin are considered to erosional-tectonic type with glacial treatment. Their formation occurred in the Neogene, and even during the glacial epoch they did not become covered completely by ice. Hydrology of these lakes shows that the feed to the lakes comes from snow to the extent of 50%, the remainder coming from rain and groundwater. The duration of the ice cover depends on the size of the lake and depth.

On average it lasts for 211–248 days and on large deep lakes ice cover starts in November to the first days of December. The thickness of the ice depends on snow deposits but maximum thickness generally occurs in April before the thaw in mid-May to the end of May and reaches thicknesses of about 1.15–1.20 m. The period of opening (or ice break) generally takes from 10 to 20 days and ice cover is finally cleared by the beginning of July. The temperatures of large mountain lakes are above zero from May until October/November with maximums occurring in July with values of 8–9°C in shallow lakes and 4–5°C in large deep water lakes.

Finally, Eastern Siberia has a distribution of both fresh and salty lakes. For example, in lakes of the Vilyui Basin (Kempendjaiskie), the extraction of salt has been carried out for many years. The ecological condition of the majority of Eastern Siberia lakes is safe enough, however, some lakes of Plateau Putorana experience significant anthropogenic loading.

Lakes of the Baikal Mountain Country

The Baikal Mountain country is in the southeast of Siberia. The country comprises block mountains, elevation 2,999 m, aged from Precambrian to Mesozoic, combined with crystal rocks. The climate is sharply and extremely continental, the northern part being situated in a taiga zone, the southern in a steppe zone.

There are some 1,000 lakes in this region, in territory of Irkutsk district alone there are about 4,000 lakes. The best known is Lake Baikal, which is second only to the Caspian Seas. The following facts describe Lake Baikal:

- (a) Surface area 31,500 km²
- (b) Volume 23,000 km³, 22% of world reserves
- (c) Length 676 km
- (d) Average width 48 km
- (e) Depth 1,741 m, making it the deepest in the world
- (f) Elevation 1,285 m
- (g) Catchment 557,000 km²
- (h) Evaporation 6%
- (i) Water level characterized by small fluctuations 20–144 cm, highest in September and lowest in April
- (j) Seiches amplitude of level fluctuation 12–14 cm.
- (k) Temperature of water in benthonic layers 3.1°

The history of Baikal goes back 25 million years. Its origin is dominated by global rift structure and high seismic activity. Recent geophysical research has shown that Baikal may be an incipient ocean based on the speed of the dispersion of the banks by 2 cm per year, which is how continents have dispersed in Africa and South America. There are 22 small islands on the lake, the largest of which is Olkhon Island. In morphological respects, the lake can be divided into three basic hollows

1. Northern, having greatest depth over 983 m
2. Southern, greatest depth 1,436 m
3. Middle, greatest depth 1,741

The lake is fed by 336 rivers, the largest of which is River Selenga, whose catchment is almost 83% of the total catchment. The single outlet is the River Angara. In 1959 the Irkutsk hydroelectric station was built by damming the river at the outlet, whereupon, water level of the lake was raised by approximately 1 m.

The chemical composition of the lake water is as follows:

1. Water has weak mineralization
2. Water is soft
3. Average sum of ions about 95 mg/l
4. Average transparency 26 m maximum 40 m.
5. Color varies by place and season – dark blue with transparency 30 m
6. Significant changes of lake temperature within a year affect only the top 200–250 m
7. The period of autumn circulation begins with a decrease in temperature of the top layers of up to 4°

Lake Baikal freezes late – in January and in winter, with conditions of sharp temperature fluctuation, numerous cracks, from several millimeters up to meters in width, form on the ice cover. Some of them are formed in the same place every year. The lake is opened only in the middle of May. Because of its unique depth, many scientific investigations are, and have been, carried out. In the case of fauna, it is known that 60% of 2,630 kinds of animals (1,550) and plants (1,080) living in the lake are endemic. Among them are golomyanka fish, seals, and omul.

Among other large lakes in the Baikal Mountain country are Bolshoi Eravnoe, Arahley, Baunt, Busany, Oron (Vitum River Basin), Gusinoe and Selenginskoe (Selenga River Basin), Oron (Irkutskaya Oblast), closed Lake Zoon-Torey, and Barun – Torey (near Mongolian border).

There are few lakes north of Vitimskiy Krai in Patomskoe and North-Baikal Plateaus. Their number rises from North-Muiskiy Ridge and, further to the south, on Vitimskoe Plateau. There are about 500 lakes in the River Vitim Basin. They can conveniently be divided into two groups: Valley lakes in wide valleys, mainly in Muisko-Kuandinskaja, and Bauntovskaja Hollows. Some lakes here have arisen as a result of tectonic hollows filling with water. Among them are the large Tsypa-Tspinskaja and Eravno-Harginskaja lake system. The largest lake of the group, Baunt, is located in Bauntovskaja Hollow in the system of Verhnjya (Upper) Tsypa, Tsypican, and Nizhnjya (Lower) Tsypa Rivers. It has a triangular shape with length about 16 km and width 9 km. The maximum depth is 33 m and the transparency is 3.5 m. An interesting feature of Bauntovskaja Hollow is the presence of a large number of hot sources (for example, Mogoyskiy Tochinskiy, Busaniyskiy). Lake Baunt is rich in fish such as “soroga,” perch, crucian, whitefish, ide, and eel-pot, and sometimes sturgeon and grayling. It is interesting to note that recently a Baikal goby has been found that was believed to have only been in Lake Baikal. It is also interesting that it is believed that more than a million years ago,

in the second half of Tertiary or at the beginning of Quaternary, there was a connection between Baikal and Baunt Lakes or that they may have been a single whole.

The largest lakes of the Eravno-Harginskoi system is Lake Big Eravnoe near the Vitim River Basin on a catchment with the Selenga River. The lake has a length of 14 km, a width of 13 km, and a depth of 5–15 m. The banks are low and covered by dense bush of cane. The lake is rich in fish, mainly pike, crucian, and perch.

Many small lakes are scattered in the Muiskaja Valley and it is reported that research has shown that all the small lakes were once one large reservoir that emptied when Vitim broke through ridges to the north. In Southern-Muiskaja Ridge there is Lake Dorong, resting in a narrow deep rocky crevice connected with the Verhnjya (Upper) Tsypa River. Lake Dorong is at elevation 1,110 m and 11 km long and 1 km in width along its full length. The lake water temperature is 6–10° and the maximum depth is 55 m.

Mountain lakes of glacial origin were formed by moraine dams left behind by glaciers. Some of them are the source of rivers or streams. Many lakes lay above a timberline. The largest is Lake Dorong and a system of Amudisskiy Lakes. In addition to these lakes is Lake Oron, located at the foot of the northern slopes of North-Muiskiy Ridge on the right bank of the Vitim River. The lake is connected by a 1 km passage to the river. The lake has a length of 19 km, a width of 2.25 km in the southeast, and 6.5 km in the northeast part. The bottom of the lake falls abruptly on the southern side, where the depth reaches 184 m.

Lakes of Shilka and Argon Basins represent, in most cases, the remainder of a now-vanished large water bodies. Among them there are dried up lakes such as Zoon-Torey (surface area 258 km²) and Barun-Torey (surface area 528 km²), located in the south on the border of Russia and Mongolia. Some lakes in the Argun River basin are mineralized through dry climate conditions. There are also salty and bitter-salty lakes. The salt composition of the lake waters of Doron, Onon, and Borgaiskoe contain soda because the rocks are basically igneous. Lake Doron has long since been a source of the extraction of soda. Soda lakes, in freezing, evolve a crystal soda that looks like a milky white color on ice. There are a group of bitter-salty lakes in the Chita area and Borzinskiy lakes. In the southern part of the River Argun Basin between two rivers (Agi and Onon) the group of Aginsky Steppe lakes represent shallow, saucer-shaped hollows filled with water, some of them drying up in summer. There are also many shallow lakes in the River Amur flood plains. In winter many of them completely freeze.

The ecological condition of most of the lakes network of the Baikal Mountain Country is generally good. Lake Baikal of course attracts a great deal of attention from specialists, academics, and tourists. The main lake pollution is connected with Rivers Selenga and Upper Angara (about 2/3 sulfates, more than 80% chlorides, and 70% organic substances). The pollution was caused by paper and pulp,

chemical, and petrochemical industries. Waters coming from Mongolia have higher content of mineral oil and ions of copper and phenols, all many times above the maximum concentration limits.

Lakes of Priamurie

Priamurie is a part of Priamuro-Korean, noted for its mountain relief with vast mountainous depressions on the Paleozoic and Mesozoic structures. The climate is from monsoon to sharp continental, and taiga landscape gives way to pretaiga and deciduous Far Eastern landscapes. There are some thousand lakes, mostly small but large lakes are found in the valleys of the Rivers Razdolnaya and Ussury and on the Prikhankayskaya Plain.

The largest lake of Priamurie is Lake Khanka, located in the Ussuri Basin on the border of Russia and China. Its surface area is about 4,100 km² and catchment 16,890 km² with 15,370 km² in Russia, the remainder in China. The lake is shallow with a mean depth of 4.5 m and maximum of 10 m. The River Sungacha, a tributary of the Ussuri, issues from the lake. Lake Khanka has abundant vegetation consisting of various species of sedge and reed and is well known for the migration of water fowl, of which there are about 300,000–350,000 ducks, 100,000–130,000 geese, and 3,000–5,000 swans; rare species of Japanese cranes (20–25 families), Daurskia cranes, 10–15 families of far eastern white storks, and Bera porchard also have their nests in the Khanka Basin.

Among other large lakes with a surface area more than 100 km² are Lakes Chukchagirskoe, Bolshoe Kizi, Orell, Udy, Everon, Bolon, Hummy, and Chlya. Their basins represent fault depressions with alluvial deposits. Most of the lakes are of shallow depths not exceeding 3–8 m and most are connected by channels to the Amur River. The significant part of Priamurie lakes is located near the sea and has saltish or salty water.

The condition of Priamurie lakes and their catchment has considerably worsened in recent years due to industry and chemical pollution. Other problems include land tenure and the degradation of a soil-vegetation cover over water-marsh grounds. Rice growing in the areas of Prikhankajskaja Plain is a powerful spur to the economy and crops have significantly increased over the past 10 years. Unfortunately, this has meant considerable amounts of fertilizers over the catchment of Lake Khanka leading inevitably to deterioration of the lake water quality due to elements of copper, zinc, phenols, and mineral oil and pesticides.

Lakes of the Kamchatka-Kuril

The Kamchatka-Kuril country is part of the Pacific Ocean folded zone in which tectonic movement still continues. Kamchatka at the elevation of 4,750 m has a volcanic origin and the Kuriles Ridge contains a series of volcanoes, where the glaciation is advanced. The Kamchatka Peninsula has a large variety of lakes of glacial and floodplain origin. Sea lagoons are found in the coastal areas but the most exotic lakes are of volcanic origin where the craters

have been filled with water. Examples are the large volcano-tectonic lakes of Kamchatka – L. Cronockoe, surface area of 245 km², depth 306 m, and L. Kurilskoe, surface area 77.1 km² and a depth of 128 m. Along the Pacific coast are the following lakes: Karymskoe of volcanic origin with a water surface of 10.3 km², Bolshoe, Kalygar, surface area 5.0 km², Bolshoe Medvedka, surface area 5.0 km², Ostrovnnoe, surface area 5.4 km², and Nerpichje, surface area 13.2 km². Each of these lakes has unique beauty and aquatic inhabitants. The banks are steep or flat and covered with rich vegetation. The lakes are pristine with red salmon, blue-black salmon, roach, and keta.

The main characteristic of volcanic lakes is the presence of power and material balance of a hypogene source, which may have a significant influence on the hydrodynamical and hydrochemical processes of the lake. In this connection, a number of volcanic lakes comprise concentrated acid instead of water. For example, the volcanic lake Malyi Semenchak in Troitskogo. The temperature of this opaque lake ranges from 27° to 42° in a solution of sulfuric and hydrochloric acid of middle concentration. The dimensions of the lake are somewhat surprising, having a width of 0.5 km and a depth of up to 140 m. There is a strong suspicion that the lake has suffered a recent eruption. Another lake, Lake Karymskoe, suffered the effects of an eruption to the Karymskiy volcano only 6 m away. The eruption lasted 18–20 h and caused 100 underwater explosions in the lake, creating a “tsunami” with waves as high as 15 m. The lake literally boiled and all life in the lake was lost. The lake is probably the largest acid lake in the world. In a valley of the upper and middle courses of the Kamchatka River there are the small spring-fed lakes (Domashnee, Ushki, etc.); their occurrence is connected with lava-flows.

The plant life in Kamchatka lakes is fascinating, with algae and organisms living in a burning solution. Nevertheless, numerous colonies of multicolored thermophilic organisms float on a surface of hot lakes with temperatures of 30–70°. The life of fresh lakes is multiform also, for example, swans are able to live here.

The various flora and fauna of volcanic lakes frequently participate in a biogeochemical cycle of substance and layers of the ashes introduced from other volcanoes are found. In bottom sediments there is an accumulation of many chemical elements, and highly mineralized waters quite often represent liquid ore. Many lakes are rich in medical mud due to microbe processing of vegetation. Lakes Utinoe and Sakscoe have each about a meter layer of medical hydrosulfuric mud.

Lagoon lakes often formed at the mouths of rivers but generally elongate in parallel with the coast. These lagoon lakes are rich in bird life and fish such as flounders from sea entry, starfish and jellyfish, and an abundance of salmon from the sea concentrating in estuaries and river mouths. The greatest of them is shallow Lake Nerpichje (the area about 500 km²), located in a mouth of Kamchatka River. The largest estuaries on the Pacific

coast are Zhupanovsky, with a surface area of 24 km², and Semjachiksky, with a surface area of 10 km². On the Bering Sea coast are the following lagoons: Malamvajam, Ukinskaja, Haylulinskaja, Ivashkinskaja, Makarievskaja, and Kaum. On the Okhotsk Sea the following estuary-type lagoons, Mikojanovsky, Brumka and Moroshechnaja. Lakes Nizovtcevo, Krasikovskoe, Azabachie, and Kursin, have been formed as a result of the transfer of river alluvium from the Kamchatka River.

In Kuriles, there are some hundred lakes of various origin, some due to volcanic activity. There are small, deep mountain lakes occupying craters of extinct volcanoes. For example, Tomari-Yama on Kunasiri Island, Lake Usen-Ko on Krenitcina peak, having a depth of 200 m, and others. Waters of these lakes have yellowish color because of sulfuric sources inflow. The coast is occupied by larger lakes, usual lagoons type, with length up to 10 km. They are normally connected to the sea by small channels. The coast of Sakhalin Island abound in lakes or lagoons separated from the sea by narrow spits. Some lakes that have been cut off from the sea have become fresh water bodies.

RUSSIAN WATER RESERVOIRS

Victor P. Saltankin
 Water Problems Institute of the Russian Academy
 of Science, Moscow, Russia

Description

Water reservoirs of Russia are artificial water basins more than one million cubic meters in volume. Ponds are artificial water basins less than one million cubic meters in volume. The first water reservoir in Russia is the Alapayevsk reservoir, which is five million cubic meters in volume and 2 km² in area. It was constructed in 1704 on the Neiva River in the Urals. During the period from the eighteenth to the beginning of the twentieth century several dozens of small water reservoirs were built for industrial water supply ([Figure 1](#)).

Large-scale construction of water reservoirs started in the second half of the twentieth century, after the Great Patriotic war (1941–1945). However, even before the beginning of the war, two very important water reservoirs were built. The first one was the Ivankovsk reservoir – the main source of water supply for Moscow (60%), built on the Upper Volga in 1937. The dam of the reservoir is located in the area of the town of Dubna. The second was the Rybinsk reservoir on the Volga River regulating the river runoff of the Upper Volga. It was filled up to the design reference marks during 1941–1947. In 1941, when there was real threat of fascist occupation of the Russian capital, the Rybinsk hydroelectric power station was the sole source of electric supply for Moscow.

Russian Water Reservoirs, Figure 1 Reservoirs of Soviet Union (1979). The contemporary scheme of Russia's reservoirs is absent. I – reservoirs' volume more than 100 km³; II – 50–100; III – 25–50; IV – 10–25; V – 5–10; VI – 1–5; VII – 0.1–1 km³. The periods of construction of the reservoirs: VIII – before 1951; IX – 1951–1960; X – 1961–1970; XI – after 1970.

Large-scale construction of water reservoirs occurred during the 1950s–1970s of the twentieth century. It was carried out in the European part of the country in the framework of the well-known plan of the State electrification of Russia developed by the Russian specialists in the beginning of the twentieth century, even before the October revolution of 1917.

In 2010, there were about 2,700 water reservoirs in Russia, each more than one million cubic meters in volume, and 26,300 lb. From the total number of water reservoirs there were 252 reservoirs more than ten million cubic meters in volume, and 86 artificial water basins more than 100 million cubic meters in volume. There were 49 large water reservoirs of federal (state) importance, more than 1 km³ in volume each. These are mainly the reservoirs of Volga-Kama and Angara-Yenisey cascades, as well as lake-reservoirs, where the useful regulated volume of water is provided through the increase of water level in lakes by means of hydraulic engineering constructions.

The share of Russia's water reservoirs in the modern world fund of artificial reservoirs amounts to 14% by total volume and 16% by the total area. Parameters of Russia's

reservoir fund (total volume, active capacity, area) approximately correspond to those of the USA.

Russia is in the top ten countries of the world with the biggest number of constructed dams and, correspondingly, of water reservoirs. These ten countries include USA, Canada, China, Brazil, India, Turkey, Spain, France, and Japan.

Total volume of the water reservoirs in Russia amounts to nearly 1,000 km³, active capacity is 435 km³, the total area of the water surface is 115,400 km², including 52,400 km² of the lake areas where the water level is raised artificially by means of hydraulic engineering constructions. Total length of the Russian water reservoirs' coastline is 60,000 km, which is 1.5 times more, than the coastal line of the seas washing Russia (40,000 km).

Water reservoirs in Russia are irregularly distributed by the economic regions of the country. There are 72 reservoirs in the Northern economic region, 32 ones in the Northwest, 206 in the Central region, 74 in the Volga-Vyatka region, 575 in the Central Black Earth region, 612 in the Volga region, 408 in the North-Caucasian region, 394 in the Ural region, 121 in the West-Siberian

region, 68 in the East-Siberian region, 79 in the Far Eastern region, and 9 in the Kaliningrad region.

The water reservoirs constructed on the rivers are more widely distributed, as well as lake-reservoirs. The highest degree of the river flow regulation is in the rivers of the European territory of the country where the water-consumers and water-users have deficiency of water resources during some periods and years. Currently, 40% of the Volga River, 50% of the Don River, and 68% of the Ural River flow water is regulated by reservoirs. Total active capacity of the regulated flow of the rivers in the European part of Russia amounts to 161 km³, including 35 km³ on the rivers of northern, and 126 km³ of the southern watershed slope.

The whole modern fund of the country's water reservoirs was built within the period of existence of the USSR (Union of the Soviet Socialist Republics, 1917–1991). Large-scale hydraulic engineering construction, including building of water reservoirs, in Russia is caused by the fact that rivers in their natural condition cannot satisfy the increased economic and social needs for water supply. Construction of reservoirs in the most developed part of the country (southern, central, and northwest regions of the European part of the Russian Federation, the Ural region, the Caucasus) is caused by the fact that these regions are supplied with insignificant part of resources of river runoff. Irregularity of river runoff by seasons of the year and between the years also exists.

The most developed economic regions of the country occupying 27% of the area of the Russian Federation are supplied with about 4% of water resources. In many regions of Russia more than half of annual runoff happens in two–three spring months, and the runoff of low water years is much less (up to three times) of the average annual.

Parameters of Russian water reservoirs widely vary: capacity ranges from one million cubic meters to 169,000 million cubic meters, area – from 1 km² to 5,900 km², length – from 1 km to 565 km, depth in the dam parts – from 10 m to 150 m, and width of large reservoirs in Russia reaches 35–40 km.

Large reservoirs in Russia are mostly used in a complex – for the sake of water-power engineering, thermal engineering, atomic engineering, irrigation, industrial and economic-potable water supply, water transport, fishing industry, and recreation. In 2010, about 400 hydroelectric power stations operated in the country, 118 of them have capacity more than 25 mW. The share of hydroelectric power stations in the generation of electric power in Russia amounts to about 20%. Total capacity of hydroelectric power stations in Russia amounts to about 45 million kW. Approximately 100 reservoirs provide water for thermal and atomic power stations generating hundreds of billions of kilowatt-hours. Forty-four of them, with total capacity more than 50 gW, provided with special cooler reservoirs, develop 350 billion kilowatt-hours of electric power. Hydropower potential of Russia amounts to 850 billion kilowatt-hours, which is second largest in the world after China, though the degree of

its exploitation in Russia amounts to 19%. In the European part of the country it is exploited on 50%, in Siberia – on 10%, and in the Far East only on 4% (Table 1).

In Russia 18 million hectares of the soil is irrigated, 8 million hectares of which – on the basis of the reservoirs' water resources.

Total extent of internal waterways of Russia amounts to about 140,000 km, while that of the water reservoirs is 12,000 km. Construction of water reservoirs in Russia allowed to radically reconstruct the waterways on the main navigable rivers (Volga, Kama, Don, Yenisey, Angara). Construction of water reservoirs allowed to form the uniform deepwater system of waterways on the European territory of the country, with the guaranteed depth of 3.4 m, and made it possible to use large-capacity vessels with displacement up to 5,000 t.

Almost half (45%) of the total volume of water reservoirs in Russia and one third of the water surface area (35%) is in Siberia and the Far East, where very large and the world's largest water reservoirs have been constructed (Bratsk, Krasnoyarsk, Boguchansk, Baikal, Sayano-Shushensk, Ust-Ilimsk, Zeysk, Viluyusk, Novosibirsk reservoirs).

Energy was the main decisive factor in creation of large water reservoirs in Russia. After the end of the Great Patriotic war (1945) there was the sharpest need to increase the production of electric power for restoration of the national economy that was destroyed on 60–80% during the war. The chosen way was construction of heavy-duty hydroelectric power stations on the large European rivers of the country – Volga, Kama, Don. For a number of technical and economic reasons in 1950s–1960s of the twentieth century thermal engineering could not develop adequately fast in Russia. The atomic engineering at that time only started to be formed as power branch. Powerful hydroelectric power stations and large water reservoirs were created on the plain rivers of the European part of the country. Design development and creation of large hydroelectric power stations in Siberia on the rivers with high hydro-energy potential were carried out simultaneously, first of all, on the Angara and Yenisey.

Construction of water reservoirs in the European part of the country had a complex orientation – production of electric power, improvement of water transport operating conditions, industrial and municipal water supply, flood control, fishing industry, and recreation. The highest population density is on the Russian plain where 60% of the population of Russia resides on the 12% of the country's territory; about 70% of Gross National product is manufactured in this region. The water reservoirs created in the European part of the country provide industrial water supply for metallurgical, chemical, pulp and paper, and energy branches of economy. Water cargo transportation on the united deepwater system of Russian waterways amounts to several hundreds of million tons a year.

Recreational use of water reservoirs acquired wide circulation, especially for short-term (5–7 days) and week-end (1–2 days) recreation. Tens of millions of

Russian Water Reservoirs, Table 1 Russian largest water reservoirs

Russians visit water reservoirs for rest and sports. It is caused by the fact that many large cities of the country are located on the banks of water reservoirs, no less than 60 million people (about 45% of all the country's population) resides in the zone of 1-hour transport accessibility to water reservoirs.

Many water reservoirs of Russia have great value for domestic and industrial water supply of city agglomerations and large cities of Russia. It is caused by the fact that resources of underground waters having better quality of water in comparison with surface sources (rivers and lakes), as a rule, are not sufficient to meet the needs of the multi-million population of large cities and water-capacious branches of economy and industry (first of all, thermal and atomic engineering, metallurgical and chemical industry, agriculture). In Russia about 70% of the total water consumption volume is provided by surface sources. Dozens of large cities of Russia with the population more than 100 thousand people are supplied with water from water reservoirs. These are the cities located on the banks of water reservoirs of Kama, Volga, Don, Kuban, Ob, Angara, and Yenisey. Resources of non-regulated river runoff, as a rule, are not enough for the guaranteed water supply of the population, economy, and industry. The most typical example in this respect is the city of Moscow, the capital of Russia, which is located on the bank of the Moskva River, rather small in annual flow. The population, economy, and industry of the city had no serious prospects of development based on rather limited river and underground flow resources. In the end of the 1920s exploratory and design study was carried out for solving the problem of water supply of the Russian capital. The decision was made on building Ivankovsk water reservoir with seasonal regulation of the Upper Volga flow (total volume 1.12 km^3 , active capacity – 0.8 km^3 , area – 327 km^2 , length – 125 km), and on the construction of the Moscow Canal (the former name “the Moscow-Volga Canal”) 128 km in length for delivery of a part of the Volga flow to the Moskva River. These constructions were built in the shortest terms – in 5 years during 1932–1937. Until now the world hydraulic engineering practice considers this engineering project and its realization as one of the best in the world. In 1935, the population of Moscow did not exceed three million people; in 2010 it was officially estimated as nine million people, though many experts on town-planning consider, that the real current population is no less than 12 million people. Construction of Ivankovsk water reservoir and the Moscow Canal allowed to provide city development 75 years ahead. With construction of the Moscow Canal the city of Moscow became the port of five seas: Baltic, White, Azov, Black, and Caspian when there occurred an opportunity to use cargo vessels with displacement up to 5,000 register tons. Currently, Moscow is supplied with up to 2.5 km^3 of water per year using this channel, and the potential of this hydraulic engineering system is still far from being exhausted, and it maintains its importance in the twenty-first century. The system of

water reservoirs for water supply of Moscow further developed, in 1950s–1970s new water reservoirs on the Moskva River and its tributaries, as well as the new Vazuza hydraulic engineering system was built.

In 2011, the system of Moscow water supply includes 16 water reservoirs and 2 channels. This allowed to create one of the world's most reliable systems of a large megacity water supply. Reliability of Moscow water supply by different estimations amounts to 95–97%. It means that in 95–97 years of a 100, necessary amounts of water consumption and water disposal are provided; and if there is a shortage of water, industrial water-consumers are limited first; there were no such cases during the period from 1937 to 2011. All large water reservoirs of Russia carry out the functions of flood control, however, there are two main water reservoirs of flood control value. First of them, Zeysk reservoir was created in 1975 by Zeysk hydroelectric power station's dam, 116 m in height. Its total volume is 68.4 km^3 , active capacity – 38.2 km^3 , area – $2,420 \text{ km}^2$, length – 290 km , maximum width up to 40 km , and maximal depth about 100 m . Zeysk water reservoir has exclusively important flood control value. After its creation 75 thousand hectares of new fertile flood plane and terrace lands were developed, average annual damages from flooding in the Zeya River plain below the power plant dam decreased 3–4 times. The construction of large Bureysk water reservoir in the Far East of the country on Bureya River, tributary of the Amur River, is being completed. Flood control value of the water reservoir is even greater: 120–150 thousand hectares of agricultural lands will be protected from frequent flooding.

The use of water reservoirs for fishing industry in Russia is widely developed. According to official fishery statistics, the annual yield in various years was estimated in the range of 30–50 thousand tons per year. These seem underestimations since Russia has not managed yet to properly solve the problem of illegal fishing, the so-called poaching, which by virtue of different reasons increased greatly. By different expert estimations, it is considered that illegal fishing (without permits, licenses, and authorizations) can reach up to 50–100% of the total yield recorded by official statistics.

In creation of large water reservoirs in Russia the interests of a fishing industry were always considered and complex actions on the development of fishing were prepared. However, real fish yield in the absolute majority of water reservoirs turned out 3–15 times below the design levels for a number of reasons. Modern fish productivity of the most important water reservoirs of the country varies in a wide range from 1 kg per hectare (water reservoirs of Siberia) up to 40 kg per hectare (Tsimlyansk water reservoir on the river Don, the most productive in Russia). Three to ten kinds of fish are covered by fish industry in various water reservoirs of the country, and the industry volume of low value kinds reaches 60–80% of the total yield. One of the characteristics of Russia is that the so-called commercial fishery is carried out on water reservoirs of the country; in the majority of the developed

countries of the world commercial fishing is not carried out, but nonprofessional (recreational) fishing is widely developed.

Water reservoirs of Russia are widely used in the recreational purposes for mass leisure and sports of the population. The range of recreational activities is rather wide and totals several dozens of summer and winter activities. Recreation both in the recreational institutions (sanitariums, recreation centers, camps, leisure bases) and in the framework of riverside tourism and boating is popular. General recreational potential of Russia amounts to no less than one billion visits per year, especially considering weekend recreation of the country's urban population. Creation of many water reservoirs improved the recreation opportunities on reservoirs of this type, especially regarding the range of recreational activities. In many industrial regions of the country the water reservoirs are the main recreational objects. For example, the modern recreational potential of eight water reservoirs of the Volga cascade considering, first of all, ecological restrictions, amounts to 400 million visits per year. The situation in two of the Russian Federation constituent territories – in Moscow and the Moscow area – is indicative. These regions have very few large natural water objects (rivers and lakes) suitable for mass recreation of tens millions of people. The main objects of water recreation for inhabitants of Moscow and the Moscow region are the water reservoirs of the water supply system of the Russian capital of Russia. During the Soviet period recreational zones for the inhabitants of 23 municipal areas of Moscow were created that one could reach by railway, automobile, and water transportation.

The storage coefficient, that is, the ratio of active capacity of a water reservoir to the volume of long-term annual average runoff at the dam site varies for different water reservoirs of Russia within a wide range from 0.1 to 0.8. Water reservoirs carry out long-term, seasonal, weekly and daily regulation of river runoff.

Total water exchange coefficient in water reservoirs varies within wide range from 8 to 10 times annually (high-current water reservoirs) up to 1 time every 2–3 years (low-current water reservoirs). It is determined by many factors: parameters of a water reservoir, water inflow to the reservoir, and orientation of water resources' use.

Annual amplitude of water level fluctuations in water reservoirs of Russia is within the range from 1 m to 50 m.

The three-dimensional system of currents in large water reservoirs of Russia is rather complex, the main types are discharge currents, wind and wave currents, compensatory and drift currents. The speed of currents in the surface layer of water (0.5 m) decreases from 0.5 to 1.0 m/s in the upper part of water reservoirs to 0.10–0.20 m/s in the dam parts. The speed of bed currents is insignificant and amounts to several centimeters per second. Complex velocity profile of the currents is indicative, that is, the change of their vectors from the water surface to the bottom.

As a whole, water reservoirs of Russia can be viewed as transitional and accumulative hydro-ecological systems of transitional type water object between river and lake ecosystems. This determines the formation features of water quality, types, and ecological condition of bottom soil, orientation, and intensity of hydro-biological processes, structure, and variety of various types of water ecosystems within one large water reservoir.

There were long-standing discussions in Russia on whether the water reservoirs improve or worsen the quality of water, since the reduction of current speed and the decrease in turbulent exchange were traditionally considered as negative consequences of water quality formation. However, more experts lean toward complex evaluation of water reservoirs' positive influence on the quality of water. Such positive evaluation is based on the fact that the processes of intense wind-wave and convective mixing of water take place in water reservoirs; powerful water ecosystem produces plenty of oxygen, and, finally, the bottom soil accumulates large quantity of polluting and highly toxic substances. Back inflow of pollution from bottom soil to the water environment as a result of desorption processes is qualified as the process of secondary pollution. This problem was also actively discussed in Russia during last decades. Many large water reservoirs of federal and regional value in Russia have already been used for 50–60 years, and no secondary pollution has yet been noted.

On the most important water reservoirs of the country the monitoring of water quality by scores of hydrological, hydro-chemical, and hydro-biological parameters is carried out. For large water reservoirs strongly pronounced spatial-terminal heterogeneity of water quality parameters is characteristic, when concentration distinctions in various locations of a reservoir may reach 10–100 times. In Russia 1,750 parameters is a norm for economic-potable water supply. The most typical polluting substances in water reservoirs are easily oxidizable and hardly oxidizable organic compounds, petrochemicals, phenols, heavy metal compounds, and synthetic surface-active substances. Excess of the average annual content of the named compounds may reach 2–10 times in relation to maximum permissible concentration. There are areas of water with insignificant, average, and essential level of pollution in each of the large water reservoirs, especially during the winter period. As a rule, it is caused by the discharge of insufficiently purified service and industrial wastewater in the water reservoirs. For example, on the Volga water reservoirs there are more than five thousand of such drainage outlets.

There are about 15 types of bottom soil complexes in the water reservoirs of Russia, the speed of bottom sediments accumulation is usually insignificant and amounts to 0.5–4 mm per year. Strength of bottom sediments in dam areas can reach 1.5–2 m. Estimated sedimentation term in the majority of large water reservoirs amounts to several hundreds years.

High phytoplankton species diversity is characteristic for water reservoirs of Russia; up to 400 taxons are defined on a number of reservoirs. Intensive phytoplankton development, the so-called "blooming" of water, is usually connected with development of diatom and cyanobacteriae. In weak phytoplankton development its biomass amounts to 0.5–9.9, in intensive 10–99, and in hyperblooming more than 100 g/m³.

Average biomass of zoobenthos in 25 largest water reservoirs changes within a range from 1 to 42 g/m², and average biomass of zooplankton varies within range from 0.2 to 4.8 g/m³.

The degree of water reservoirs' weediness by the highest aquatic vegetation (deep, floating, and aero-aquatic) amounts to 0.4–30% of the water area.

In 1967, the world's largest river reservoir – Bratsk – was formed in Russia on the Angara River with capacity of 169.7 km³, area 5,467 km², maximal depth of 150 m, and length 1,020 km. Kuybyshevsk water reservoir on the Volga River built in 1957 is the largest reservoir in the Europe. Its volume is 57.3 km³, area 5,900 km², maximal depth – 41 m, and length – 510 km.

Creation of the Irkutsk (Baikal) water reservoir on the Angara River, the only river flowing out of the lake Baikal, led to increase of the lake level by 1.8 m. This caused extremely negative ecological consequences for the lake ecosystem regarding the activation of coast destruction processes and sharp reduction of population of the main industrial fish of Baikal – the well-known Arctic cisco. All these consequences during several dozens of years caused active indignation of ecologists and the public. Now, at the level of the Government of the Russian Federation the decision was made that the increase of Baikal water level more than 1 m is not allowed; special operating mode of the Angara-Yenisey hydroelectric power stations' cascade and water reservoirs is settled for this purpose. The most powerful hydroelectric power station of Russia is Sayano-Shushensk (6,400 mW) on the Yenisey river; the dam of 230 m in height forms Sayano-Shushensk water reservoir. Tragic events of August 2009 were related to this hydraulic engineering complex, when as a result of failure on the pressure head pipeline of one of the turbines, there was an instant water inflow in the machine hall, destruction of four turbines, and death of 72 people. It is the largest technogeneous accident related to hydraulic engineering constructions in Russia. No less than 5 years and costs of about five billion US Dollars are required for the station restoration.

Top ten of the world's most significant cascades of water reservoirs include the Volga-Kama (11 water reservoirs) and Angara-Yenisey (7 water reservoirs).

Creation of large water reservoirs in Russia essentially influenced practically all components of environment in the zone of influence of artificial reservoirs. It is related to flooding of a part of water-producing territories; flooding of coastal territories; climatic changes; formation of essentially different hydrological structure; new types of ecosystems; shore destruction; influence on flora and fauna; reorganization of industrial, economic, and transport infrastructure; and change of social and economic conditions of the population's life.

The area of flooding by construction of water reservoirs is estimated as 46,100 km² that is 0.27% of the total territory of Russia. Among the lands are woods, fields and meadows, and other lands, including settlement territories. No less than one million of people were moved from the zones of flooding and adverse influence on coastal territories.

Water reservoirs are natural-technical systems, and significant financial assets are necessary for the maintenance of their satisfactory engineering, technical, and ecological conditions. The main modern problem of the Russian water reservoirs is development and realization of the system complex of activities connected with the water reservoirs' operation mode, minimization of negative influences on environment, and improvement of social and economic conditions of living in the water reservoirs' influence zones. Water reservoirs of Russia are a part of the country's national riches. Prospects of creating new large hydro-units and water reservoirs in the nearest 25 years remain unclear due to high capital intensity of creating this type of objects and long terms of design and creation (usually no less than 15 years).

SAKI, LAKE (CRIMEA, UKRAINE)

Rhodes W. Fairbridge (Deceased)

Description

Located at 45°07'N, 33°33' E near the west coast of the Crimean peninsula in Ukraine, Lake Saki is salty due to the high E:P ratio of the local climate.

It has become celebrated in paleoclimatology following a deep boring in the annually layered sediments, which average only 1–2 cm in thickness for each layer (varve). It may be noted that the Swedish term “varve” refers to an annually layered couplet of one dark-colored seasonal layer reflecting low precipitation and one light-colored layer representing the season with higher precipitation. In general, the rainfall intensity varies in phase with that of Central Asia but inversely with respect to Central and Western Europe.

A count of the varves by Schostakowitch in 1934 is reproduced in Lamb (1977, Figure 16.24, p. 408), together with a rainfall scale following a suggestion by Brooks (1949). The sequence goes back to 2294 B.C. Due to the thinness of the layers, some may, however, have been lost in the counting, but for long periods, this can be checked by repeat statistical sampling.

Time-series analyses have been undertaken by Xanthakis et al. (1995), using several different methods (MESA, or maximum entropy spectrum analysis; Blackmun–Tukey power spectrum analysis; PSA; Fourier FFT; autocorrelation). Interesting clusters of periodicities emerge over the entire series, notably 20–25, 44–46, 57–67, 120–130, and 200–250 years. Similar clustering is seen in long-term analysis of ¹⁴C flux levels in ten millennia of tree rings, and in magnetic and auroral records.

An earlier analysis of the Lake Saki varves based on less sophisticated methods by Dewey (1964) recognized a 17 1/3-year cycle, which periodicity he had also identified (with C. S. Jarvis) in flood stages of the River Nile during the first millennium. This periodicity appears to be a beat frequency developed by the two principal lunar tidal parameters, the 18.03-year “Saros” perigee-syzygy period and the 8.849-year apsides cycle, i.e., 17.3769 year.

Following the calculations by Brooks (1949, p.299), reproduced as a graph in Lamb (1977), the rainfall at Lake Saki around 2100–2300 B.C. fluctuated around 45–56 cm/year, but for a long interval, 2100 B.C. to A.D. 700, it hovered about 38–42 cm/year; it then rose to a moisture peak of 48 cm/year about A.D. 800, fell, and then rose again to 50 cm/year in 1,100–1,300, falling to 43–45 cm/year till the present. Elsewhere in Russia, Lamb noted a very marked increase in continentality, 1,300–1,450, but after that, it is interesting that Lake Saki displayed no evidence of the Little Ice Age. In general, Lamb notes the Lake Saki record oscillates in an inverse sense to that in western and northern Europe. Particularly, dry spells occurred in the 12th, 10th and 6th centuries B.C. and around A.D. 1250, just when western Europe was particularly wet (Lamb, 1977, p.408).

In view of the 21st century interest in extreme events (floods or droughts), the Lake Saki record provides specific data. In the 21st century B.C. when varve thickness average was 17 mm, in one uniquely distinctive year, 2177 B.C., it was 110 mm. Another, in 2150 B.C., was 230 mm, in 889 B.C. was 110 mm again, and in A.D. 805 was 220 mm. A hydrologic engineer would probably categorize these as “thousand-year floods.” Each was a “singularity” and *not* part of a trend.

In contrast, the dry spells or droughts tend to be drawn out, e.g., in 1873–1813 B.C., there were only 24 out of 60 years that produced a varve more than 10 mm thick. Immediately following the 889 B.C. flood, there followed,

in 888–870, 18 dry years with several varves as thin as 5 and 6 mm. Similar dry spells occurred in A.D. 1296–1292, citing some notable examples.

SATELLITE DATA AND LAKES

Lennart Jönsson
Water Resources Engineering, Lund University,
Lund, Sweden

Description

The use of data obtained from sensors on satellite platforms implies that electromagnetic radiation emitted from objects on the ground is detected by a satellite sensor and analyzed in terms of different ground properties. Most sensors are passive, relying on emitted visible, near-, or thermal infrared radiation. Active sensors emit microwaves which are detected after backscattering on the ground. Different characteristics of satellites and sensors make them useful for different purposes – the revisit time for images of a certain area, the spatial resolution of images, the image area, the spectral resolution, the resolution of the detected radiation – and these properties have to be considered for possible lake applications. Most sensors are developed for land or ocean applications not considering possible, special demands for lakes, which means that the lake applications are somewhat restricted.

Main lake satellite data applications are related to:

- Surface area determination
- Water levels
- Water quality determination in terms of secchi depth, turbidity, chlorophyll contents

- Hydrodynamic processes (upwelling, mixing processes, thermal bars, etc.)
- Ice conditions

The application of water quality determination in terms of biological constituents such as algae (phytoplankton pigments, colored dissolved material [gelbstoff, etc.]) is of course important and of practical use. A problem is that water leaving radiance, related to water quality parameters, reaching the satellite sensor is commonly only about 10% and often less than 1% of the total sensor-detected energy. This means that reliable atmospheric correction is critical. The water quality signals from algae, for instance, can also be masked by high concentrations of gelbstoff, suspended inorganic particles, detrital material (case 2 waters) in contrast to open oceanic waters. Consequently, derived relations between satellite data and water quality parameters are site-specific. Reported applications mostly refer to large lakes. Generally speaking, the use of satellite data for monitoring lake properties and characteristics is less common than some other applications basically due to the fact that lakes often have a small surface area and that the optics of water and its constituents is complex.

Determination of surface area extent of (mostly large) lakes is an obvious and straightforward application utilizing a near-infrared spectral band as almost all of the incident light energy in this wave length band is absorbed at the water surface. Thus a lake surface is depicted as a distinct black area in optical satellite imagery. The shrinkage of Lake Aral and Lake Tchad has thus been studied using NOAA AVHRR (1.1-km spatial resolution), Landsat MSS (80-m) and TM (30-m) imagery, MODIS data (at least 250 m). Lake Poopo in Bolivia is an example of a small lake with a significantly changing surface area being studied with Landsat TM data with 30-m spatial resolution.

Active microwave satellites (synthetic-aperture radar, SAR) such as ERS-1 and ERS-2 with spatial resolutions of nominally 30 m can also be used for delineating lake water surfaces as a smooth water surface will not reflect any incident energy back to the satellite. SAR technology has the great advantage of not being hampered by clouds in contrast to optical imagery.

Studies on lake water levels have been reported for some large lakes such as Lake Kivu in Africa, using the radar altimeters on ERS-2 and ENVISAT with a footprint of a few kilometers.

Lake surface water temperatures (the uppermost few mm:s) have been determined using the two thermal infrared spectral bands of the NOAA AVHRR instrument (resolution 1.1 km) or the single thermal band of Landsat TM (resolution 120 m). The former utilizes the split-window technique offering a better temperature resolution (<1°C). Hydrodynamic phenomena can be studied indirectly using the surface temperatures. One example is given by Lake Ladoga where the existence and the propagation of the thermal bar (the 4°C isotherm) during the

Satellite Data and Lakes, Figure 1 Lake Ladoga. Sea surface temperature from May and June respectively. Boundary between light blue and dark red depicts the location of the thermal barrier (4°C) (After Malm 1994).

spring/early-summer heating of the lake was studied using NOAA AVHRR data, [Figure 1](#). Upwelling of cold water in a lake can also be studied, which has been reported from Lake Tanganyika in Africa, a phenomenon of practical interest for fisheries. A good correlation between pan evaporation and NOAA AVHRR surface water temperatures has been reported from Lake Okeechobee, Florida.

Derivation of different aspects on water quality from satellite data has been tried in many cases. The water depth visibility in terms of secchi depth has been determined in terms of Landsat 5 TM data using a combination of reflectance in band 1 (blue) and band 3 (red) respectively for a lake in Missouri, USA. An extensive study from Lake Erken, Sweden, surface area 24 km², described the use of Landsat TM data, band 1–4 algorithms, for deriving chl-a and SPM (total suspended particulate matter) contents. Construction of the algorithms using simultaneously obtained in situ data showed a good agreement between satellite and in situ data.

The more recent SeaWiFS sensor on the SeaStar satellite is primarily devoted to ocean applications with a spatial resolution of 1 km and with spectral bands devised for chl-a, gelbstoff, and suspended sediment mapping. Among reported lake tests are Lake Balaton, Hungary, Lake Constance, Switzerland, and Lake Erie, USA.

The SPOT 1, 2 satellites offer a very high spatial resolution, 20 m in multispectral mode and 10 m in panchromatic mode making delineation of small lakes possible. The three multispectral modes do not seem to be well adapted to lake studies, although efforts have been made to determine chl-a.

Ice freeze-up and ice breakup in a large number of Canadian lakes have been studied using NOAA/AVHRR-derived surface brightness temperature and SPOT/VGT near-infrared reflectance during a 10-year period. Comparison with in situ observation showed a good agreement.

SEDIMENTATION PROCESSES IN LAKES

Lars Håkanson

Department of Aquatic Sciences and Assessment,
 Institute for Water and Environment, Swedish University
 of Agricultural Sciences, Uppsala, Sweden

Definition

- Allochthonous – From outside (often used to characterize materials transported from the drainage area to a lake).
- Anoxic sediment – Sediment devoid of free oxygen.
- Autochthonous – Originating from inside the lake.

Benthos – Organisms living in or on the river or lake bed.
Bioturbation – Mechanical mixing, for example of bottom sediments due to living organisms.

Catchment – The drainage basin which channels precipitation into a lake or single outflow.

Diffusion – The movement of atoms or molecules from a region of higher concentration of the diffusing species to regions of lower concentration.

Eutrophic – A lake rich in nutrients, usually resulting in high productivity.

Load – The flux (transport) from the catchment to the lake.

Partition coefficient K_d – The ratio between the amount of radionuclide attached to suspended matter per unit of mass and the amount of dissolved radionuclide per unit of volume of water.

Phytoplankton – Plant members of the plankton.

Primary productivity – The total production by photosynthetic and chemosynthetic activity of organic substances.

Resuspension – The remobilization of particles from the sediments of a water body by the action of water movement.

Sediment – The matter which has fallen to the bottom of a water body.

Sedimentation rate – The amount of matter deposited on the bottom of a water body per unit of surface and time.

Stratification – Division of lake water masses into horizontal layers with different physical and chemical properties.

Suspended matter – Matter suspended in lake and river waters.

Trophic level – The hierarchical level that an organism occupies in the food chain. The group of organisms that occupy the same level in the food chain.

contamination and relate natural fluxes to anthropogenic fluxes, and hence also to get realistic expectations of remedial measures. Sedimentological processes are fundamental parts of mass-balance models since they quantify internal transport processes in lakes, such as sedimentation, resuspension, and mixing. The approaches originally presented by Vollenweider (1968) have been followed by many others. The mass-balance approach to lake eutrophication has played a paramount role in lake management.

During the last 10 years, there has been a “revolution” in ecosystem modeling. The major reason for this development is, in fact, the Chernobyl accident (Håkanson, 2000). To follow the pulse of radiocesium through ecosystem pathways has meant that important fluxes and mechanisms have been revealed. It is important to stress that many of these structures and equations are valid not just for radiocesium in lakes, but for most types of contaminants, e.g., for metals, nutrients, and organics, in most types of aquatic environments.

The predictive power of any mass-balance model for any given substance depends on the structure of the model and the numerical values and equations applied in the model. Generally, there are many ways to structure mass-balance models depending on the target y -variable to be predicted and the scale of the modeling, i.e., if calculations are done on a short-term basis (minutes-days) or long-term basis (years to centuries) or if site-typical information (using partial differential equations) or area-typical (whole lake) approaches are being used (and ordinary differential equations).

It is not possible to understand how lakes function without a basic knowledge of the transport processes that exist in all lakes and apply to all substances. Figure 1 gives a compilation of such processes. These processes have the same names for all lakes and for all substances:

- Sedimentation is the flux from water to sediments.
- Resuspension is the advective flux from sediments back to water.

Background of transport processes in lakes

Mass-balance models are since long fundamental tools in aquatic sciences to gain knowledge about processes and fluxes, in water management to identify sources of

Sedimentation Processes in Lakes, Figure 1 Illustration of general and fundamental transport processes to, within, and from lakes.

- Diffusion is the flux from sediments back to water triggered by concentration gradients.
- Mixing appears in stratified lakes and is the transport between deep-water areas and surface water areas.
- Mineralization is decomposition of organic particles by bacteria.
- Primary production is creation of living suspended particles from dead matter by sunlight.
- Burial is the transport of matter from the lake biosphere to the geosphere, often of matter from the technosphere.
- Outflow is the flux out of the lake of water of everything dissolved and suspended in the water.

Figure 2 exemplifies these sedimentological processes using data from Lake Geneva, Switzerland, which is large (503 km²) and deep (mean depth 72 m). Some typical characteristics related to sedimentation in lakes may be identified:

- Most fluxes appear with clear seasonal patterns.
- Mixing is a dominant flux, and upward mixing is smaller than downward mixing.
- Burial is smaller than sedimentation because there is substantial diffusion of phosphorus from the accumulation-area sediments, especially in the summer time when the lake has a relatively stable thermal stratification.
- The riverine inflow is driving the conditions (the trophic situation) in the lakes and this flux is significantly larger than the atmospheric precipitation of phosphorus.
- Resuspension is relatively small in this deep lake.
- There are two fluxes removing phosphorus from the lake, and the outflow is bigger than the burial.

The water depth that differentiates the surface water (epilimnetic) part of the lake from the deep water (hypolimnetic) (at 23 m in Lake Geneva) could, potentially, be related to (1) water temperature conditions and the thermocline, (2) vertical concentration gradients of dissolved or suspended particles, (3) wind/wave influences and wave characteristics, and (4) sedimentological conditions associated with resuspension and internal loading. There are several ways to characterize vertical heterogeneities in lakes. From a mass-balance perspective, it is necessary to work with clearly defined depths, volumes, and substance concentrations.

If one can find a relevant way of defining the water depth separating the surface water layer from the deep-water layer, this will also open possibilities to calculate outflow in a simple, operational, and mechanistic manner for water and everything dissolved and suspended in the water since the outflow is given by:

$$F_{\text{out}} = Q_{\text{out}} \cdot C_{\text{SW}} \quad (1)$$

F_{out} = outflow of the given substance in dissolved or particulate form in g X per week or month.

Q_{out} = water transport out of the lake in m³ per week or month.

C_{SW} = the concentration of the substance in the surface water in g X/m³.

The concentration of the substance in the surface water, C_{SW} , is defined from the following ratio:

$$C_{\text{SW}} = M_{\text{SW}}/V_{\text{SW}} \quad (2)$$

Sedimentation Processes in Lakes, Figure 2 Monthly fluxes of phosphorus in Lake Geneva, Switzerland (using the LakeMab-model; see Håkanson and Bryhn, 2008).

M_{SW} = the mass or amount of the substance X in the surface water compartment (g X).

V_{SW} = the volume of the surface water compartment (m^3).

The volume of the surface water compartment, in turn, is a function of the lake area, the depth separating surface water from deep water, and the form of the lake (as given by the hypsographic curve).

A proper definition of the water depth separating the surface water layer and the deep-water layer is also important in quantifying sedimentation, because sedimentation of particulate matter from the surface water to the deep water, and from the deep water to the lake bottom, is related to the settling velocity of the suspended particles (v in m/week or month) and the mean depth of the two respective compartments, D_{SW} and D_{DW} . Basically, sedimentation (F_{SWDW} , i.e., sedimentation from surface water to deep water) is given by:

$$F_{SWDW} = M_{SW} \cdot (v/D_{SW}) \cdot PF \quad (3)$$

where PF is the particulate fraction, the only fraction subject to gravitational sedimentation.

Defining the surface water and the deep water layers also means that one can define upward and downward mixing.

This section will also present an approach to calculate those areas of the lake bed where resuspension is likely to occur (the areas of fine sediment erosion and transport, the ET areas; see Figure 3). The depth separating areas where resuspension is likely to prevail from the areas with continuous sedimentation of fine material is called the wave base.

The thermocline

To use the thermocline as the key criteria to differentiate between the surface water and the deep water is certainly the most classical approach (Wetzel, 2001). But that does not necessarily imply that it is operational in contexts of mass-balance calculations. This is demonstrated in Figure 4 using data from Lake Erken, Sweden. For single sites after longer periods without strong winds in the summer, one can certainly see clear thermoclines. However, for many sites over longer periods of time (weeks and months), it is generally very difficult to define the critical water depth requested in mass-balance calculations – any water depth between 0.1 and 18 m in Lake Erken, which has a maximum depth of 23 m, could be used! The data shown in Figure 4 for Lake Erken are included here to emphasize that for this lake, and for lakes in general, the thermocline may be a poor alternative for the water depth separating areas where resuspension is likely to occur from the deeper accumulation areas. Water temperatures do not provide consistent information to define the boundary between surface water and deep water.

Suspended particulate matter: a definition

The total amount of a substance or a group of substances in the water is often separated into a particulate phase, the only phase subject to gravitational sedimentation, and a dissolved phase, generally the most important phase for direct biouptake. Operationally, the limit between the particulate phase and the dissolved phase is generally determined by means of filtration using a pore size of

Sedimentation Processes in Lakes, Figure 3 The ETA diagram (Erosion-Transportation-Accumulation; for more information, see Håkanson and Jansson, 1983) illustrating the relationship between effective fetch, water depth and bottom dynamic conditions. The wave base (D_{wb}) can be used as a general criterion to differentiate between surface water and deep water in lakes.

Sedimentation Processes in Lakes, Figure 4 Temperature data from Lake Erken, Sweden (unpublished data for the summers of 1997 and 1998 from ongoing monitoring) and illustration of the wave base in this lake. Each line represents the temperature profile at the monitoring station at a given sampling occasion. (From Håkanson et al., 2004.)

0.45 μm . Evidently, this is an operational approach and many colloidal particles will pass such filters and are, hence, operationally included in the dissolved fraction, although they are not truly dissolved in a chemical or biological sense. Suspended particulate matter (SPM) as determined in this way by filtration, drying, and weighing, is sometimes also referred to as SSC, the suspended sediment concentration. Filtration is often a justifiable method from sedimentological, ecological, and mass-balance modeling perspectives.

Figure 5 classifies SPM according to origin. Many factors are known to influence SPM in aquatic systems. The most important factors are:

1. Autochthonous production (i.e., the amount of plankton, feces, etc., in the water – more plankton, etc., means a higher SPM).
2. Allochthonous materials, such as the amount of colored matter (e.g., humic and fulvic substances).
3. The amount of resuspended material.

These three factors are not independent: High sedimentation leads to high amounts of resuspendable materials; high resuspension leads to high internal loading of nutrients and increased production; a high amount of colored substances means a smaller photic zone and a lower production; a high input of colored substances and a high production would mean a high sedimentation, etc.

SPM is generally a complex mix of substances of different origins with different properties (size, form, density, specific surface area, capacity to bind pollutants,

etc.). SPM may be divided into an organic fraction (POM) or an inorganic one (PIM, particulate inorganic materials). Total organic matter (TOM) is generally divided into particulate (POM) and dissolved (DOM) fractions. Normally, POM is about 20% of TOM, but this certainly varies among and within systems. Normally, about 4% of POM is living matter and the rest is dead organic matter (detritus). About 80% of TOM is generally in the dissolved phase, and of this about 70% is conservative in the sense that it does not change due to chemical and biological reactions in the water mass.

Sedimentological processes

From this background, the aim of the following section is to define and explain some fundamental sedimentological processes starting with sedimentation.

In quantifying lake sedimentological processes, lakes are often divided into four zones: Surface water, deep water, ET areas (areas where processes of fine sediment erosion and transport dominate the bottom dynamic conditions), and accumulation areas (A areas). The following abbreviations for such fluxes are generally: F for fluxes (g/month), C for concentrations (g/m^3), R for rates ($1/\text{month}$), and M for masses (= amounts in g). Fluxes from one compartment to another are denoted, for example, F_{SWDW} for sedimentation from surface water (SW) to deep water (DW). The resuspended matter can be transported either back to the surface water (F_{ETSW}) or to the deep water (F_{ETDW}). How much will go in either

Sedimentation Processes in Lakes, Figure 5 Classification of particles in water (see Ostapenia, 1985).

direction is regulated by a distribution coefficient (DC) calculated from the form of the lake.

Sedimentation of suspended particles depends on:

1. A default settling velocity, v_{def} which is substance specific and related to the type of carrier particle. Examples are 12 m/year for illite clays, the carrier particles for radiocesium (Håkanson, 2000) or 72 m/year for planktonic materials (Håkanson and Boulion, 2002). The v value is changed into a rate (1/month) by division with the mean depth for the surface water areas (D_{SW}) for sedimentation on the ET areas above the wave base and by the mean depth of the deep-water areas (D_{DW}) for sedimentation in deep-water areas (the A areas) below the wave base.
2. The concentration of suspended particulate matter (SPM in mg/l) will influence the settling velocity. The greater the aggregation of suspended particles, the bigger the flocs and the faster the settling velocity.
3. The amount of resuspended matter will settle faster than the primary materials. The resuspended particles have already been aggregated and they have also generally been influenced by benthic activities, which will create a “gluing effect.”

The wave base is often determined from the ETA diagram (Erosion-Transportation-Accumulation). This approach (Figure 3) focuses on the behavior of the cohesive fine materials settling according to Stokes' law (see Eq. 4 and Figure 6). The grain size and/or the

Sedimentation Processes in Lakes, Figure 6 The relationship between the settling velocity (v_s) of spherical particles) in water, particle diameter, and particle density (at 20°C) as given by Stokes' law.

composition of the material are often used as criteria to distinguish different sediment types. One can also differentiate between different sediment types by means of functional criteria (like erosion, transportation, and accumulation) of coarse sediments (friction material) or fine sediments (cohesive material). In geoeological contexts, it is common to focus on the finer materials most easily set in motion/resuspension and having the highest capacity to bind pollutants. In defining the bottom dynamic conditions (erosion, transportation, and accumulation), this work uses the following definitions:

- Areas of erosion (E) prevail where there is no apparent deposition of fine materials but rather a removal of such materials, e.g., in shallow areas or on slopes; E-areas are generally hard and consist of sand, gravel, consolidated clays, and/or rocks.
- Areas of transportation (T) prevail where fine materials are deposited periodically (areas of mixed sediments). This bottom type generally dominates where wind/wave action regulates the bottom dynamic conditions (see Figure 3). It is sometimes difficult in practice to separate areas of erosion from areas of transportation.
- Areas of accumulation (A) prevail where the fine materials are deposited continuously (soft bottom areas). These are the areas (the "end stations") where high concentrations of pollutants may appear (see Table 1).

The generally hard or sandy sediments within the areas of erosion (E) often have a low water content, low organic content, and low concentrations of nutrients and pollutants (see Table 1). The conditions within the T-areas are, for natural reasons, variable, especially for the most mobile substances, like phosphorus, manganese, and iron, which react rapidly to alterations in the chemical "climate" (given by the redox potential) of the sediments. Fine materials may be deposited for long periods during stagnant weather conditions. In connection with a storm or a mass movement on a slope, this material may be resuspended and transported up and away, generally in the direction toward the A areas in the deeper parts, where continuous deposition occurs. Thus, resuspension is a most natural phenomenon on T areas.

It should also be stressed that fine materials are rarely deposited as a result of simple vertical settling in natural aquatic environments. The horizontal velocity is generally at least 10 times larger, sometimes up to 10,000 times larger, than the vertical component for fine materials or flocs that settle according to Stokes' law.

The particles settling on accumulation areas (A areas) are, by definition, not further resuspended by physical forces. However, such particles can be eaten by zoobenthos, and zoobenthos by fish, so these particles can be transported up to the lake water again in this manner. They can also be transported by migrating zooplankton between the sediments and the water column. These

Sedimentation Processes in Lakes, Table 1 The relationship between bottom dynamic conditions (erosion, transportation and accumulation), and the physical and chemical character of the surficial sediments of Lake Vänern, Sweden. particles will also be mineralized and decomposed by sediment-living bacteria and then the newly formed dissolved phase can migrate up to the lake water phase by diffusive processes. Bioturbation, i.e., the mechanical mixing of sediments by sediment-living organisms, can also contribute to the transport of settled particles both back to the water and downward to the biologically passive sediments.

Generally, various types of zoobenthos live in sediments down to about 5–15 cm sediment depth (see Figure 7). This upper part of the sediment column is biologically active in the sense that the bottom fauna can influence the physical, chemical, and biological conditions of the sediments and cause bioturbation. However, the larger animals (macro- and meiofauna) generally die if the oxygen concentration becomes lower than about 2 mg/l. This will stop the bioturbation and laminated (layered and unmixed) sediments may appear. The continuous sedimentation will cause the sediment layer to grow upward so that the bioturbation limit, i.e., the limit between the upper biological layer and the lower biopassive (or geological) layer moves upward.

Many polluting substances have a considerable particle affinity. This means that the behavior of all substances with a particular phase in aquatic systems is influenced

by SPM. In addition, the retention of a given substance in a system will be governed by the turnover time of the water, i.e., the longer the water turnover time, the larger the proportion of the initial load retained within the system.

A very important part of most mass-balance models for chemical substances is the distribution coefficient. The distribution coefficient is also often called the partition or partitioning coefficient and gives the particulate fraction (PF) or the dissolved fraction (DF = 1–PF). The organic particulate fraction and the colloidal fraction may be subject to mineralization by bacterioplankton. Figure 8 illustrates the very important role that the PF-value plays for the concentration of phosphorus in water and for sedimentation of phosphorus. It is evident that the PF-value influences the concentration in lake water: The higher the particulate fraction, the less in dissolved form, the higher the sedimentation, and the lower the concentration in water, and vice versa. This is a general principle valid for all substances. PF = 1 for SPM.

Geochemically, fine, cohesive materials behave differently compared to coarse (friction) materials. From the basic Stokes' equation for settling particles (Eq. 4), as well as for convenience, the limit between coarse and fine materials can be set at a particle size of medium silt.

Sedimentation Processes in Lakes, Figure 7 Bioturbation and laminated sediments. Under aerobic (= oxic) conditions zoobenthos may create a biological mixing of sediments down to about 15 cm sediment depth (the bioturbation limit). If the deposition of organic materials increase and hence also the oxygen consumption from bacterial degradation of organic materials, the oxygen concentration may reach the critical limit of 2 mg/l, when zoobenthos die, bioturbation ceases, and laminated sediments appear (Figure modified from Pearson and Rosenberg, 1976).

Sedimentation Processes in Lakes, Figure 8 Illustration of the important role of the particulate fraction of phosphorus in mass-balance calculations (annual simulations for a lake with an area = 1 km²; mean depth = 10 m; catchment area = 10 km²; mean annual precipitation = 650 mm/year; mean tributary concentration = 26 µg/l of total phosphorus; and a settling velocity of 5 m/year for the particulate fraction).

Stokes' law expresses the settling velocity (v) as:

$$v = \frac{(d_w - d_p \cdot g \cdot d^2)}{(18 \cdot AV \cdot FR)} \quad (4)$$

v = the settling velocity (usually in cm/s)
 d_p = the particle density (usually in g dw/cm³; g dw = gram dry weight)
 d_w = the density of the lake water (often set to 1 g ww/cm³; g ww = gram wet weight)
 g = the acceleration due to gravity (980.6 cm/s²)
 d = the particle diameter (in cm)
 AV = the coefficient of absolute viscosity (obtained from standard tables; 0.01 poise at 20 °C)
 FR = the coefficient of form resistance (set to 1 for spheres; Hutchinson, 1967)

Stokes' law (Stokes, 1851) is depicted in Figure 6. The behavior of materials that follow Stokes' law (i.e., particles with a diameter between about 0.01 and 0.0001 cm) differs from the coarser friction material and the still finer material. The sedimentological behavior of the friction material is closely linked to the grain size of the individual particles; the sedimentological behavior of the very fine materials is governed by Brownian motion. These latter particles are so small that they will not settle individually, but will do so if they form larger flocs or aggregates which are dense enough to settle according to Stokes' law. The cohesive materials that follow Stokes' law are very important,

since they have a great affinity for pollutants. This group includes many types of detritus, humic substances, and plankton. All play significant roles in aquatic systems.

The settling velocity (v) of a given particle, aggregate, or particulate pollutant, and its distribution in an aquatic system, depends on the density, size, and form of the particle (and on the hydrodynamics of the flow of water in the system). If the particle density, d_p , is close to 1, if the form factor, FR, is large, and if the diameter, d , is small, the settling velocity, v , may be very small. If v is close to 0, the particle or aggregate is conservative in the sense that it may not be deposited in the system. In many lakes, Cl and alkalinity are often conservative substances, and color, organic matter, total-P, Si, particulate-P, and SPM are more reactive.

Summary/conclusions

Lake sediments are an important, integral part of the lake ecosystem. They reflect changes in land-use and lake characteristics and are often regarded as an historical archive. They also affect the present structure and function of lake ecosystems. Suspended particulate matter (SPM) in lakes mainly emanate from tributaries (allochthonous matter), from living and dead matter produced in the lake (autochthonous matter), or from resuspended materials. SPM regulates the transport of all types of water pollutants in dissolved and particulate phases; it regulates water clarity and the depth of the photic zone, and hence also primary and secondary production; it regulates bacterioplankton production and biomass, and hence also mineralization, oxygen consumption, and oxygen concentrations; and it regulates sedimentation, and hence also the use of sediments as an historical archive, e.g., of water pollutants. These matters are discussed in this chapter. The aim of the information given is to structure existing knowledge on the factors regulating variations among and within aquatic systems of suspended particulate matter in a rational manner. This knowledge is fundamental for an understanding of the function and structure of aquatic systems.

SEDIMENTS, FLUSHING FROM RESERVOIRS

W. Rodney White
 Wallingford, Oxfordshire, UK

Introduction

There are around 40,000 large reservoirs worldwide used for water supply, power generation, flood control, etc. Between a half and 1% of the total storage volume is lost annually as a result of sedimentation, and 300–400 new dams need to be constructed annually just to maintain current total storage. However, increasing populations and increasing consumption per capita mean that the demand for storage is rising inexorably despite the increasing use of alternative sources and the more efficient use of water. The introduction of flushing facilities in some old dams, where appropriate, and in the design of new dams could help to minimize this need for additional storage.

The benefits attributable to dams and reservoirs, most of which have been built since 1950, are considerable, and stored water in reservoirs has improved the quality of life worldwide. These benefits can be classified under three main headings:

Irrigation: About 20% of cultivated land worldwide is irrigated, some 300 million hectares. This irrigated land produces about 33% of the worldwide food supply. Irrigation accounts for about 75% of the world water consumption, far outweighing the domestic and industrial consumption of water.

Hydropower: About 20% of the worldwide generation of electricity is attributable to hydroelectric schemes. This equates to about 7% of worldwide energy usage.

Flood control and storage: Many dams have been built with flood control and storage as the main motivator,

e.g., the Hoover dam, the Tennessee Valley dams, and some of the more recent dams in China.

In many areas of the world, the life span of reservoirs is determined by the rate of sedimentation which gradually reduces storage capacity and eventually destroys the ability to provide water and power. Many major reservoirs are approaching this stage in their life.

One way of preserving reservoir storage is to flush sediments through purpose built outlet works within the dam. This technique can be applied to existing dams (with adaptation of the engineering works) and to new dams. However, the technique is only effective under certain favorable conditions and is not universally applicable. The alternative is to build more dams to replace the depleting storage of the existing stock. However, there are fewer and fewer good dam sites available, and new dams can have serious environmental and social consequences.

A recent study carried out by HR Wallingford (White et al., 1999 and White, 2001) has evaluated where and when the flushing of sediment may be an appropriate method of sustaining reservoir storage. The study included the following aspects:

- An assessment of the scale of the problem of reservoir sedimentation
- An estimation of the volume of storage that is likely to be required to meet continuing demand
- A review of the current state of knowledge of mechanism of sediment flushing from reservoirs
- A review of the worldwide experience of sediment flushing from reservoirs
- Identification, in general terms, of the areas of the world where flushing is likely to be most useful

This contribution summarizes the lessons learned in the HR study without giving all the supporting evidence. Readers are referred to the HR report and the Thomas Telford book for full coverage of the work.

There is a distinction between sediment flushing and sediment sluicing. Sediment flushing is concerned with the removal of sediments which have settled in the reservoir at a previous time, whereas sediment sluicing is concerned with passing sediments straight through the reservoir during times of flood. The distinction is sometimes difficult to make. But, generally, sediment flushing is used to remove sediments up to and including sands and gravels, whereas sediment sluicing removes only the finer fractions. It is the sands and gravels which determine the ultimate sustainable volume of any reservoir, and hence, the following sections predominantly relate to *sediment flushing* (Figure 1).

Review of sedimentation in reservoirs

World storage: The best estimate of world storage in reservoirs (excluding natural lakes used as storage for power and irrigation) is approx. 7 000 km³.

Sediments, Flushing from Reservoirs, Figure 1 Reservoir sedimentation, Zimbabwe.

Distribution of storage: The worldwide distribution of existing storage and storage under construction as determined from the ICOLD Register (1998) is shown below:

Region	Number of dams	Gross storage (km ³)	Fraction of world total	Average size of reservoir (M.m ³)
N. America	7,205	1,845	29%	256
S. America	1,498	1,039	16%	694
N. Europe	2,277	938	15%	412
S. Europe	3,220	145	2%	45
Sub Saharan Africa	966	575	9%	595
North Africa	280	188	3%	652
China	1,851	649	10%	351
S. Asia	4,131	319	5%	77
C. Asia	44	148	2%	3,364
Southeast Asia	277	117	2%	424
Pacific Rim	2,778	277	4%	100
Mid. East	895	224	3%	250
World total	25,422	6,464	100%	254

The Americas together with Northern Europe and mainland China account for 70% of the existing world stock of reservoir storage.

Demand for more storage: The world population in 1999 is estimated to be 6,000 million, growing at an annual rate of 1.5%. This rate of growth is forecast to decline in the coming decades giving an estimated population in 2050 of 10,000 million.

Water demand is expected to continue to grow at a faster rate than predicted by population growth alone. Much of this demand will be satisfied by increased surface and groundwater abstraction and water reuse, and no direct linkage between overall demand and water storage can be assumed.

From the rates of growth for population, water consumption, estimated irrigation, and hydropower requirements, the demand for new storage is estimated as:

Region	Demand for new storage (km ³)		
	2000–2010	2010–2020	2020–2030
Europe	50	50	55
South and Central America	465	495	425
Africa	165	205	250
Asia and Oceania	315	280	215
Total	995	1030	945

Loss of storage: The rate of loss of storage for a given reservoir is dependent on the sediment yield from the catchment which, in turn, is dependent upon the rate of erosion and the transport, by water, of the sediment within the catchment. In regions where the catchments have remained stable, e.g., Northern Europe and North America, the rate of loss of storage is sensibly constant. In regions where deforestation has occurred, the rate of catchment erosion and consequently the rate of loss of storage increase.

The highest rates, in percentage terms, of loss of storage are found in the smallest reservoirs and the lowest rates in the largest. Of the 1,105 reservoirs documented, 730 have a storage volume of less than 1,233 million cubic meters and an average rate of loss of storage in excess of 1% per annum. At the other extreme, 23 of the reservoirs have a storage volume in excess of 1,233 million cubic meters and an average rate of loss of storage of 0.16% per annum. The worldwide average for the loss of storage due to sedimentation is between 0.5% and 1.0% per annum – a very significant amount.

Factors which influence viability and efficiency of sediment flushing

For effective flushing the following factors need to be considered and satisfied:

Hydraulic conditions required for efficient flushing: Riverine conditions must be created in the reservoir for

a significant length of time. The reservoir level must be held low throughout the flushing period, possibly with minor fluctuations in level to activate sediment movement. To achieve this:

- The hydraulic capacity of the bypass must be sufficient to maintain the reservoir at a constant level during the flushing period.
- Flushing discharges of at least twice the mean annual flow are required.
- Flushing volumes of at least 10% of the mean annual runoff should be anticipated.

Quantity of water available for flushing: There must be enough water available to transport the required volume of sediment. This has the following implications:

- Reservoirs where the annual runoff is large compared with the volume of the reservoir are best suited for sediment flushing.
- A regular annual cycle of flows and a defined flood season provide optimum conditions for sediment flushing. This favors sites in monsoon areas and sites where flood flows are generated by annual snowmelt in the spring and summer months.
- A balance must be achievable between the significant quantities of water required for sediment flushing and water required to satisfy demands at other times of the year – for irrigation and hydropower, for example.

Mobility of reservoir sediments: Sediment sizes are an important factor in determining whether the quantity of water available for flushing will be adequate to remove the desired quantity of sediment from the reservoir.

- Deposited coarse sediments are more difficult to remove than fine sediments. These sediments progress from the upstream end of the reservoir, and the toe of the foreset slope reaches the dam well into the life of the reservoir. The sustainable volume achievable by sediment flushing depends on the nature of the deposited sediments and other factors.
- The sediment sizes in transport in rivers entering a reservoir can be of paramount importance in determining the success of flushing. From the point of view of achieving a sediment balance, a large factor is desirable between the sediment sizes being transported as suspended bed material load in the rivers entering the reservoir and the sizes found in the river bed material. Such conditions are typical for gravel rivers with a widely varying bed material composition. In large rivers, this situation is found where the longitudinal bed gradient is between, say, 0.002 and 0.001. In smaller rivers, the equivalent range may be 0.005–0.002.
- From the point of view of sediment size alone, delta deposits of fine sand and coarse silt are the most likely to produce success in flushing a reservoir. Coarser

material may inhibit a sediment balance, and finer material will deposit in the body of the reservoir outside any incised channel and so will not be available for reworking during flushing.

Site specific factors: The most suitable conditions for flushing are to be found in reservoirs which approximate in shape to the incised channel which develops during flushing. Long, relatively narrow reservoirs are better suited to flushing than short, wide, shallow reservoirs.

Worldwide experience of sediment flushing

The HR study looked at 50 reservoirs which are being or have been flushed. In some cases the flushing was successful; in others there was little or no success. The main findings from this worldwide review, some of which confirm directly the semi-independent analysis of those hydraulic factors which favor sediment flushing, are:

- *The hydrology and sedimentology of the catchment:* The hydrology and sedimentology of the catchment need to be fully understood in the planning of flushing facilities for new or existing reservoirs and to provide the background for analyses of past sedimentation and flushing performance.
- *The storage capacity of the reservoir:* Successful hydraulic flushing is more likely to be practicable in reservoirs which are hydrologically small, with a storage capacity less than 30% of the mean annual inflow. The smaller the reservoir, the greater the chance of it being successfully flushed and the larger the likely residual storage capacity.
- *The sediment deposition potential:* Flushing is vital for the preservation of long-term storage in reservoirs where the sediment deposition potential is greater than 1–2% of the original capacity.
- *The shape of the reservoir basin:* Worldwide experience confirms that the shape of the reservoir basin can have a large impact on the practicability of effective flushing and the residual storage capacity. Narrow steep-sided reservoirs in valleys with a steep longitudinal slope are the easiest to flush. Wide valleys where the impoundment covers former floodplains can be less effectively flushed because the deposits tend to consolidate and are remote from the flushing channel.
- *The deployment of full or partial drawdown:* Full drawdown and empty flushing have been found to be much more effective than partial drawdown.
- *The low-level outlet facilities provided:* Worldwide experience confirms that, for effective flushing, the low-level outlets must be both low enough and of sufficient capacity to allow significant drawdown of water levels to be controlled during the time of year when flushing is undertaken. Proportionately larger outlets are required for flood-season sediment sluicing during the flood season than for sediment flushing at the outset of the flood season.

- *The scope for enhancements to flushing:* Fluctuations in water level and discharge during flushing are beneficial to the promotion of bank slumping, increasing the rate of sediment movement. Also, the deployment of lateral and longitudinal diversion channels has been successful in promoting flushing in reservoirs which are hydrologically large or contain significant proportions of deposition in areas remote from the main flushing channel.
- *Operational limitations:* Operational considerations, such as water and power demands, can inhibit the ability to flush successfully.
- *Downstream impacts:* Downstream impacts can act as a constraint in the planning and operation of sediment flushing. In some cases flushing may be ruled out, whereas sediment sluicing, which approximately preserves the seasonal distribution of sediment load, may be a practicable alternative during the early life of a reservoir.

Geographical areas suited to flushing

Erosion rate: The erosion rate depends on a complex interaction of the following factors:

- *Climate:* Precipitation and runoff, temperature, wind speed, and direction
- *Geotechnics:* Geology, volcanic, and tectonic activity, soils
- *Topography:* Slope, catchment orientation, drainage basin area, drainage density
- *Vegetation*
- *Land use and human impact*

Estimates of global average rates of denudation have ranged from 0.06 mm/year to 0.16 mm/year (Morris and Fan, 1998). This is equivalent to estimates of between 15×10^9 t/km²/year and 20×10^9 t/km²/year (Walling and Webb, 1983). Areas with sediment yield over 1,000 t/km²/year are 8.8% of the total land area and account for 69% of the total sediment load. Regions with less than 50 t/km²/year account for about half of the land area and 2.1% of the sediment yield.

Sediment yield: Sedimentation occurs in reservoirs when the eroded sediment is transported down the river system into the reservoir. The efficiency of the transport process is expressed by the sediment delivery ratio, which is the proportion of sediment eroded from the land that is discharged into rivers (Morgan and Davidson, 1986).

The sediment delivery ratio is generally higher for sediment derived from channel-type erosion which delivers sediment to the main channels of the transport system more quickly and directly than in the case of sheet erosion.

The poor correlation between sediment yield and erosion rates makes it difficult to estimate the sediment load entering a reservoir on the basis of the erosion rate within

the catchment (Morris and Fan, 1998). Most studies that have attempted to relate the delivery ratio to catchment characteristics have found that the delivery ratio decreases as the catchment area increases (Walling and Webb, 1983).

Climatic zones: An understanding of the precipitation regimes throughout the world may allow the definition of climatic zones based on temperature and precipitation regimes. This may permit the definition of areas of high and low erosion rates. It is difficult to classify distinct climatic zones as they tend to merge into one another rather than have sharp boundaries, but a number of general models have been produced.

There have been many climatic classifications produced, but one of the most common is based on the original Koppen classification (Pidwirny, 1999) with eight climatic regions based on four temperature zones and one moisture zone and the seasonal domination of air masses.

The eight Koppen climatic regions are as follows:

- Tropical wet
- Tropical wet and dry
- Tropical desert
- Mid-latitude wet
- Mid-latitude winter dry
- Mid-latitude summer dry (Mediterranean climate)
- Polar wet and dry
- Polar desert

Hydrological characteristics required for successful flushing: Experience has shown that low reservoir water levels provide the most effective conditions for sediment flushing. To allow water levels to be lowered requires confidence that rainfall can be relied upon to refill the reservoir. It follows that well-defined wet and dry seasons

will be favorable for a sediment flushing regime. Such a climate is defined by Koppen as tropical wet and dry.

Areas of the world which are best suited to reservoir flushing: It is not possible to define precisely which specific areas of the world will provide conditions for successful flushing. In reality there is a spectrum of conditions ranging from those sites where conditions are ideal to those sites which are quite unsuited to sediment flushing.

From the Koppen classification of climatic zones, the requirements for successful flushing are most likely to be met in the *Tropical Wet and Dry Region*. Conditions in another region may also be suitable for sediment flushing, namely the *Tropical Wet Region* (Figure 2).

Locations with these types of climates include:

- Parts of Central America extending into Brazil in South America.
- A region of central Africa from the Ivory Coast in the west to Sudan in the east would be suitable.
- Parts of central Asia including Pakistan, India, Nepal, China, Cambodia, Vietnam, and Thailand.

Costs and benefits of flushing facilities

With the current procedures for assessing costs and benefits to justify the financing of new projects, it is often impossible to build sediment flushing facilities when the dam is first commissioned. This is because sediment flushing (as opposed to sluicing) only becomes effective when the deposited sediment reaches the proximity of the dam, and in most cases, this will be many years after commissioning. The costs are up-front and the benefits are 20–30 years down the line – not a situation that impresses pure accountants! We need to find a way

Sediments, Flushing from Reservoirs, Figure 2 Reservoir sedimentation, Indonesia.

of putting a much higher value on sustainability in our justification procedures for the construction of dams.

The rejuvenation of existing reservoirs by the introduction of flushing facilities, particularly those which have lost between 40% and 60% of their original storage, is attractive in that costs are likely to be between 10% and 30% of the cost of new dams of a similar capacity.

Design implications for flushing facilities for new and existing reservoirs

Flushing facilities require extensive investigative work to establish their viability, and this will be required on a site-by-site basis. There are numerous stages for such investigations which include the following:

Site investigations: Flushing facilities have to be able to withstand high velocity flows with high concentrations of sediment. Such flows are highly abrasive, and expensive steel lining will normally be required to avoid undue damage to the structures. Hence, it is important that the site allows for the construction of relatively compact flushing facilities, either orifices within the dam itself or relatively short tunnels or channels. Energy dissipation works will normally be required at the downstream side, and it is an advantage if these facilities can be shared with other outlets such as high-head spillways or irrigation outlets. It is advantageous if the flushing facilities discharge to the downstream channel well away from any power station outlets as any local deposition of sediments will increase tailwater levels and reduce power output.

The reservoir itself requires a detailed survey to establish its topography. This is required to check whether the reservoir basin is a suitable shape for sediment flushing and also to provide input data for detailed modeling of the sedimentation process within the reservoir.

Hydrological investigations: It has been stated above that there are certain requirements for successful sediment flushing which are related to the amount of water available and its reliability year on year and season by season. Hence, inflows to the reservoir need to be established with confidence. This involves the acquisition of historical records of river flows going back at least 30 years and preferably longer. Records of river flows can often be extended further back in time by considering local rainfall records, which often go back a 100 years or more, and undertaking catchment modeling to convert rainfall into runoff.

The ideal situation for sediment flushing is an annual inflow of water of at least three times the volume of the reservoir (original volume in the case of existing reservoirs) and an annual hydrograph which shows distinct wet and dry seasons.

Sediment investigations: The amount and nature of the sediment entering or likely to enter the reservoir need to be established. This requires measurements over many years to establish the results with the confidence which is required. There are various approaches to this task. Most commonly sediment transport is measured at a gauging

station not too far upstream of the reservoir, and a relationship between flow rate and sediment transport rate is established. The long hydrological record is then used to compute the total amount of sediment passing the gauging station by integrating over the period of the record. There are some dangers in doing this because there is no unique relationship between flow rate and sediment transport rate for fine cohesive sediments, the quantities of sediment being determined by the amount being washed off the catchment, not the capability of the river to transport them. Bed load is difficult to measure and is often estimated as 10% of the total sediment load. An alternative approach is to calculate the bed load using established predictive techniques.

In the case of existing reservoirs, information about the amount of sediments entering the reservoir can be augmented by surveys of the amount and nature of the material settling within the reservoir. Care is required, however, to allow for the amount of, mainly fine, material which passes through the reservoir without deposition.

Bed material sampling should be undertaken in the reservoir and in the rivers which feed the reservoir. A sound knowledge of the nature of these sediments, including their size and specific gravity, is an essential requirement to provide inputs for numerical models which simulate sediment movement, see later.

Hydraulic modeling: Sophisticated numerical (computer) modeling of the way sediment is likely to behave within the reservoir and the amount and nature of the sediment which will be passed to the downstream reach is the cornerstone of any detailed evaluation of flushing facilities. One-dimensional models with quasi-two-dimensional simulation of the incised channel which develops during sediment flushing are the most appropriate tools. These models are computationally efficient and are capable of making long-term simulations, decades rather than hours or days. They have reached reliability levels which permit them to be used "cold" on new reservoirs which are only at the investigative stage. When used on existing reservoirs, they have the added benefit of measured sedimentation data for verification purposes.

Computer simulations of reservoirs ideally use representative, long-term sequences of water and sediment inflows to the reservoir. The models are capable of looking at the effectiveness of various aspects which affect reservoir sustainability over periods of up to 50 or 60 years, including:

- Measures to reduce the amount of sediments entering reservoirs such as catchment conservation or upstream storage.
- Measures to manage sediments within reservoirs such as variations in the operating rule curves for the reservoir. Rules which permit emptying of the reservoir annually promote movement of sediment toward the dam; rules which maintain high water levels ensure storage of sediments at the upstream end of the

reservoir and help to extend reservoir life albeit with the penalty of reduced water yield.

- Measures to evacuate sediment from the reservoir including dredging and sediment flushing.

Engineering and costs: The design of the civil works involved in all the options for helping to sustain reservoir capacity need to be estimated so that the best solution can be found.

System simulation modelling: System simulation modelling is required to evaluate the conflicting demands of hydropower production, irrigation, and other requirements and must be able to assess the impacts of the various reservoir operating strategies. The simulation model must be able to replicate the outputs of water and power under a range of operating strategies so that an optimal economic and technical solution may be identified. In addition, it must be possible to take account of the effects of other reservoirs upstream and downstream of the one under consideration.

Economic and financial analysis: The main aim of economic and financial analyses is to assist in the identification and selection of the most favorable sediment management option. For each option, the most important factor, from the economic viewpoint, is to define the “with” and “without” project cases. These will illustrate the net economic impact of the availability of water resources over time, including any seasonal variations. Evaluation of the impact of alternative investment phasing is also important.

The greatest challenge in the evaluation of projects which promote sustainability of reservoirs is to assign realistic values to the benefits of extending reservoir life. This is beyond the scope of this entry. Work, however, is progressing in this direction (Palmieri et al. 2003).

Wetlands in Slovenia

The Republic of Slovenia covers a surface area of 20,273 km² with a population of 2,046,976 inhabitants (~100/km²; SORS, 2010). Slovenia is situated in the southeastern part of the Alps and on the northernmost part of the Balkan Peninsula, bordering Italy in the west, Austria in the north, Hungary in the northeast, and Croatia in the east and south. Slovenia comprises four biogeographical systems: Mediterranean, Panonian, Alpine, and Dinaric. One of the main characteristics of Slovenia is a significant biological and landscape diversity. To a large extent, the main reasons of the diversity are different types of climate, geological structure, the diversified terrain, and large differences in altitude (from 0 to 2,864 m, 600 m being the average). From west to east, the climate changes from Mediterranean to continental and sub-Mediterranean, which is demonstrated by the annual amount of precipitation (between 2,000 and 3,500 mm in the Alps in the west, around 1,000 mm along the Adriatic Sea in the south, and around 700 mm in the east of the country). Slovenia's territory can thus be classified as humid. The water balance for the period 1961–1990 gave the total annual precipitation of 31.7 km³ (1,010 m³/s), the total annual evaporation of 13.2 km³ (420 m³/s), and the total annual runoff of 18.5 km³ (590 m³/s) (Kolbezen and Pristov, 1998). Taking into account the total area of 20,256 km² (a little more than the surface area of Lake Ontario in North America), the annual specific runoff is 29 l/s km².

Surface waters are present in Slovenia in many forms and places as shown by an inventory of wetlands (VGI, 2000) prepared according to the Ramsar Convention on Wetlands. Wetlands were found on more than 3,500 localities (Table 1), and only nearly one third of them is larger than 0.15 ha; their total area is 356.50 km², covering 1.74% of the surface. As much as 83% of the wetlands are human-made or human-conditioned ecosystems. Even taking into account flood areas, wetlands still cover less than 5% of the total area (VGI, 2000). Even though wetlands are rather small in size, they are diverse in form, and their role in landscape

^aOnly wetlands with an area >0.15 ha contribute to the total area; the rest of them contribute only to the total number of localities

^bDoes not take into account watercourses as such, only smaller wetlands along them

and ecology is an important one. Three of them (Salt Pans in Sečovelje in 1993; the Škocjan caves in 1999; Lake Cerknica in 2006) are on the Ramsar List of Wetlands of International Importance. On the other hand, wetlands are among the most endangered ecosystems. In the past, the main reasons for diminishing of wetlands were agricultural measures and river engineering works. Documented records have shown that in the period between 1772 and 1990, more than 100,000 ha of wetlands disappeared (Beltram, 1996).

General information on lakes and reservoirs in Slovenia

In Slovenia, around 1,300 water bodies of standing waters (permanent and intermittent) have been registered in a special lexicon (Firbas, 2001, p. 3). Their total surface area is 68.93 km², covering 0.3% of the surface (below the European average). Using the same criteria for the definition of a lake (i.e., area >1 ha; constant water depth; low ratio between the inflow and the total volume), then there are (without Caspian Lake) around 500,000 natural lakes and artificial lakes (reservoirs) in Europe with a total area of around 300,000 km², covering 3% of the surface in Europe, and a total volume of 3,300 km³ – one third of the surface and one quarter of the volume is the portion of the artificial lakes (Heinonen et al., 2000).

Lakes in Slovenia are of natural or artificial origin, called a lake (Slov. *jezero*), a reservoir (Slov. *akumulacija*), a pond (Slov. *bajer*), a fish pond (Slov. *ribnik*), a muddy pond (Slov. *kal*; man-made freshwater wetland in karst and coastal Mediterranean area), and a muddy pool (Slov. *lokev*; similar to muddy pond). According to Klinar (1994) in the Slovenian language, reservoirs are typically referred to as *jezero*. A list of some important lakes and reservoirs in Slovenia is given in Table 2.

A little more than one half of the lakes in Slovenia is of natural origin. The majority of these are of glacial origin (as is the case elsewhere in Europe); in some cases, the tectonics played an important role (e.g., Lake Bled). They are remnants of glacial lakes that were not fully filled in Holocene because there were no major gravel-bed rivers flowing through them.

The largest glacial lakes in Slovenia are Lake Bohinj (3.28 km²; 92.5 million m³) and Lake Bled (1.43 km²; 25.7 million m³). The total surface area of all other permanent natural lakes together does not exceed 1.7 km². Many more small glacial lakes are placed on high mountain plateaus, mainly in the calcareous Julian Alps (seven lakes collectively called the lakes Triglavska jezera; lake Krnsko jezero) in the western part of Slovenia, where water on the karst surface is scarce. Such mountain lakes are also small and shallow lakes on Pohorje in NE Slovenia (lakes Ribniška jezera, lakes Lovrenška jezera),

Slovenia, Lakes and Reservoirs, Table 2 An overview of some lakes and reservoirs in Slovenia, listed according to their area (Compiled from Gams, 1962; ES, 1990; Firbas 2001; SORS 2010)

which occasionally formed within mountain wetlands (moors or peatlands; approx. 1,500 m a.s.l.).

Between many karst intermittent lakes in Slovenia, the most famous is the lake Cerkniško jezero (Lake Cerknica)

that forms periodically on the Cerknica polje. Other large karst lakes in Slovenia have a similar hydrologic regime of periodical flooding to the one of Lake Cerknica; however, they cannot compare to it in terms of extent and duration

of flooding. Numerous karst lakes are situated on other karst poljes, e.g., lake Planinsko jezero on the Planina polje, and the lake Palško jezero and the lake Petelinjsko jezero in the Upper Pivka valley. The Upper Pivka valley represents an interesting karst area built on a sequence of limestone and alluvium that are overlaying flysch. Over the area of 50 km², at least 15 lakes are formed periodically in karst depressions and are different from Lake Cerknica that formed on a flat bottom of the Cerknica karst polje (Ravbar and Šebela, 2004). On a karstic ponor, there is the lake Podpeško jezero with a stream flowing into the lake, and the karst ponor is located at the deepest point of 47 m; the same depth is reached in much larger glacial Lake Bohinj. On a karst spring, there lies a deep dark-colored lake Divje jezero near Idrija. When the natural karst periodic lakes are fully flooded, they represent the largest water surface in Slovenia (31.51 km²).

In Slovenia, 31.01 km² are covered by reservoirs. The largest reservoirs in Slovenia are river accumulations for hydropower plants on the rivers of Drava, Sava, and Soča (Table 2). The largest among them is Lake Ptuj with 4.1 km² and is thus larger than the largest natural Lake Bohinj (3.28 km²). Many other reservoirs are multipurpose and therefore used as, e.g., retention basins for flood control, but at the same time also for enrichment of low flows, fisheries, irrigation, and recreation.

The Šalek valley is situated in the northeastern part of Slovenia with a total area of around 150 km². Due to the underground coal (lignite) mining in Pliocene sediments, a subsidence landscape was developed (more than 110 km³ in 2004; Šterbenk et al., 2004). Recently, four montanogenic subsidence Šalek lakes (lake Velenjsko jezero, lake Družmirsko jezero, lake Škalsko jezero, lake Turistično jezero) have formed with a total surface area of lakes over 2 km² and a total volume of around 40 million m³. Together, they are larger than the famous Lake Bled.

In Sečovlje on the Adriatic coast, in the second half of the thirteenth century, salt works were established on alluvium of the Dragonja river. Nowadays, in the Sečovlje salt pans, marine salt is still harvested, even though in 1993 the area was put on the Ramsar list of wetlands, being an important ecosystem for flora and especially fauna (more than 260 bird species were counted, and the area was recognized as an Important Bird Area according to the Barcelona Convention).

For the majority of standing waters in Slovenia, which are mostly on a carbonate rock base, the major ecological problem is the excessive inflow of nutrients, above all of phosphorus and nitrate (Table 3). As a result of nutrient inflow, in many lakes blooming occurs in summer time, caused by the growing of green and blue algae. The major sources are anthropological: the point sources are untreated municipal waste waters and washing away on agricultural land is the diffuse source. In reservoirs, in some cases, additionally, there was an inflow of untreated industrial waste waters, bringing heavy metals, pesticides,

and organic compounds into the water column and sediments.

In a lifetime, a lake goes through an eutrophication cycle. Among lakes in Slovenia, typical:

- Oligotrophic lakes are the lakes Triglavska jezera
- Mesotrophic lake is Lake Bohinj and nowadays Lake Bled (after remediation measures)
- Eutrophic lake is situated in the northeast of Slovenia in lowlands along the Drava and Mura rivers
- Hypereutrophic lake was Lake Bled until mid-1960s (when its remediation started); other examples are practically all ponds and fish ponds as well as the lake Sotelsko jezero and some lakes in the Pomurje region along the Mura river
- Dystrophic (peat-bog) lakes are the lakes Lovrenška jezera on Pohorje

The majority of reservoirs on Slovenian rivers are gradually filling with silt, sand, and gravel due to a relatively high sediment production in headwaters (average specific annual sediment production rate is 250 m³/km²; sediment delivery ratio to the hydrologic network is close to 0.5) (Mikoš et al., 2004). This sedimentation process is quite obvious in reservoirs on large alluvial rivers (e.g., lake Moščansko jezero and lake Zbiljsko jezero on the Sava river; lake Ptujsko jezero on the Drava river) and in many smaller gravel-bed rivers.

Many lakes and reservoirs in Slovenia have relatively small catchment areas and the water exchange is relatively slow. In summertime, there is a profound (clear) water temperature stratification, and due to the relatively warm layer of surface water, they are of tourist interest for swimming and other water sports. Due to problems with water quality in some reservoirs (Table 3), tourism has not developed as expected. On the contrary, fisheries have become a major side purpose.

Bohinjsko jezero (Lake Bohinj)

Lake Bohinj has an area of 3.28 km², a circumference of 11.35 km, a maximum depth of 45 m, and a total volume of 92.5 million m³. It is the largest natural lake in Slovenia. Lake Bohinj has the Savica stream as the main inflow (average discharge ~ 5 m³/s) and the river Sava Bohinja as the main outflow (average discharge of 8.34 m³/s). Since there are no other substantial surface inflows, more than one third of the lake outflow is generated through submerged karst springs located along the north shore. The exchange of lake water takes on an average 4 months. The catchment area of Lake Bohinj is still not fully determined due to its karst nature; it is assumed to be around 100 km², and it is 30 times larger than the lake surface. The average annual precipitation in the lake catchment area is assumed to be 3,300 mm, and the lake exhibits a nival-pluvio hydrologic regime. During local thunderstorms or longer torrential rains, it can rise very fast, and the maximum observed difference between low and high stage is 390 cm. In the period 1919–2004 on average the

lake turned into ice for 49.1 days a year. In the last two decades there is increase of the number of years without ice on the lake. The nutrient inflow into the lake is moderate because the catchment area is mainly non-urbanized and lies above the forest limit. Due to these reasons, Lake Bohinj is oligotrophic with low concentrations of phosphorus and chlorophyll *a*; only average inorganic nitrogen is somewhat above the average for oligotrophic lakes (Table 3).

Blejsko jezero (Lake Bled)

Lake Bled has an area of 1.44 km², a circumference of 6.0 km, a maximum depth of 30 m, and a total volume of 25.7 million m³. It is of paramount tourist importance for the region; it has long tourist tradition and a charming island in the middle of the lake with a church on it. The lake has only minor natural inflows from springs and one natural outflow; its average discharge from the lake is around 200 l/s. In the past, before first remediation measures to increase flow through the lake took place in 1960s, the exchange of lake water took on an average almost 4 years. It is also sheltered from winds; so the natural water circulation is limited. The catchment area of Lake Bled is 8.38 km², and it is only six times larger than the lake surface. The average annual precipitation in the lake catchment area is only 1,600 mm. The maximum observed difference between low and high stage is 56 cm, which was not even nearly reached in the last few decades. The nutrient inflow into the lake is high because the catchment area is urbanized (Bled as a tourist resort with nearly 5,500 inhabitants and 4,000 tourist beds); and pollutants come also from traffic and agricultural land. Low flow-through rate of the lake additionally reduces the self-purification capabilities of the lake. The lake is stratified with anoxic hypolimnium most of the year, except during the short period when overturn occurs and oxygen is present down to the sediment–water interface.

The water quality in the lake started to decrease early in the twentieth century with a clear decrease in 1950s. The main reason was the lack of efficient sewage, not following tourist development of the area around the lake. Inflowing nutrients stimulated the growth of phytoplankton. The growth of Cyanophyta (*Planktotrix rubescens*) not only caused long periods of “blooming” of the lake but also replenished oxygen in the lake, which started to die out. In 1964, fresh water from the Radovna river was introduced into the lake at the depth of 18 m without the expected success. Therefore, in 1982, a siphon was built to extract deep water at the rate of 240 l/s. The improvement of the sewage system in 1980s reduced the inflow of waste water by 80%. This helped Lake Bled to move from (hyper) eutrophic to mesotrophic state (Table 3).

Cerkniško jezero (Lake Cerknica)

Lake Cerknica is the largest and the best known karst intermittent lake in Slovenia. It is also an important

ornithologic ecosystem, listed among the Ramsar wetlands of international importance. In the Middle Ages, scientific ideas about the functioning of this “natural wonder,” described by J. V. Valvasor, were attracting much attention among European karst researchers. Valvasor, in his first paper (1687), gave a short basic explanation, which he further developed into a more complex, but less correct, theory (1689). The basic idea of an underground lake beneath the Cerknica one and of others inside the surrounding hills remained the same as in 1687, but the flow from one lake to another was not only through simple passages but also through at least six siphons. In the literature, authors were not recognizing the significant development in Valvasor’s ideas between both papers, as recently stressed by Shaw (2004).

Lake Cerknica can accumulate as much as 10 million m³ of water in 1 day. Regular floods can cover 20 km² or 53% of this karst polje and accumulate around 28 million m³ (Kranjc, 2002). During extreme floods, the flooded area is 26 km² and the volume 76 million m³ (Table 2). The lake is filled with floodwater within several days and then emptied in weeks. In the period 1961–1990, on an average of 79 days per year the lake was fully emptied.

SOURCE OF FRESHWATER

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

Lakes hold 90% of the freshwater on the surface of the planet and play an important role in maintaining the ecological health of the planet. They are also engines for economic growth, and the use of natural lakes as sources of freshwater is increasing. Rivers and aquifers, the main source of freshwater for human consumption, are now rarely capable of meeting future water demands from large cities and industrial centers due to either the unstableness of source or quality or shortage of their supply capacity. Under these circumstances, existing systems are being replaced by natural or man-made lakes or reservoirs. Already, in many cases, natural lakes have been dammed to enlarge the storage capacity and provide major water supplies.

The global water has a dichotomy: “too little water or too much.” Floods can be alleviated or mitigated, and reservoirs play their part in flood retention; droughts are now expected more often due to global warming and yet, fresh water seems abundant. Each year, on average, more than 1 km³ of surface water per capita enters lakes, rivers, and aquifers, but unfortunately, it does not always arrive where and when it is needed.

The facts remain, however, that over one billion people do not have access to clean water in a world population of six billion. According to the United Nations Population Fund, the world will begin to run out of fresh water by the year 2050 because of an estimated population growth to over nine billion. The projected growth will be in developing countries whose water resources are already stretched; worldwide, some 54% of the annual available freshwater is being used (two thirds for agriculture), but by 2025, it could be 70%, and if consumption reached the level of developed countries, it could rise to 90%. If this is so, the world’s water may run out before the world’s oil.

Table 1 shows the percentage of the world population having drinking water and the percentage range (it can be seen from as low as 38%).

Water-related diseases kill nearly 5,000 children every day; 40 billion working hours are spent carrying water each year in Africa alone (Figure 1); women in rural Africa spend an average of 26% of their time fetching water.

Today, over 500 million people live in 30 water-stretched countries, and by 2025, the UN expects 3 billion people will be in 48 stressed countries. By 2050, over 4 billion people will live in countries unable to meet the UN daily requirements of 50 l of water per person for drinking, washing, and cooking.

Lakes are among the most dramatic and pleasing features of the landscape. Nevertheless, many of the world’s lakes are in crisis with a myriad of problems that affect the quality of their water. Contamination of water and sediments from toxic and hazardous substances can occur from many sources (e.g., mercury, arsenic, cadmium, lead, chromium, as well as organic pollutants). Careful management of the lake is therefore required especially if the lake is dedicated to water supply. The World Lake Vision of the International Lake Environment Committee (ILEC)

has recommended the following principles for managing lake water resources and other lake uses:

1. A harmonious relation between humans and nature is essential for the sustainable use of lakes.
2. A lake drainage basin is the logical starting point for planning and management – for sustainable lake use.
3. A long-term preventative approach – to prevent lake degradation.
4. Policy development and decision making for lake management – based on sound science.
5. The management of lakes for their sustainable use requires the resolution of conflicts among competing users of lake resources.
6. Citizens and other stakeholders encouraged to participate – in identifying and resolving critical lake problems.
7. Good governance based on fairness, transparency, and empowerment of all stakeholders is essential for sustainable lake use.

It is clear, therefore, that lakes in the future will be expected to play a larger part in the provision of freshwater to supplement existing supplies from rivers and groundwater.

Water Quality for Drinking: WHO Guidelines

SOUTH AMERICA, HOLOCENE COASTAL LAGOONS

Felipe García-Rodríguez
Sección Oceanología, Facultad de Ciencias, Montevideo, Uruguay
Botany Department, Nelson Mandela Metropolitan University, Port Elizabeth, South Africa

Introduction

The data presented in this paper come from eleven sediment cores taken in five coastal water bodies of southern Uruguay (Figure 1). The full database has been published in several papers (García-Rodríguez, 2006; Inda et al.,

2006; del Puerto et al., 2006; García-Rodríguez et al., 2001; García-Rodríguez et al., 2002a; García-Rodríguez et al., 2002b; García Rodríguez and Witkowski, 2003; García-Rodríguez et al., 2004a; García-Rodríguez et al., 2004b; García-Rodríguez et al., 2004c; Bracco et al., 2005a; Rodríguez, 2006; del Puerto et al., 2008). In this chapter, a synthesis on the late Pleistocene and Holocene paleoenvironments is presented. The findings of the above papers are compared to other regional studies in Mar Chiquita Lagoon and Hinojales Lagoon (Argentina), and Los Patos Lagoon in Brazil (Figure 1), where similar paleoenvironmental studies have been carried out. Thus, a biogeographic overview on the late Pleistocene and Holocene coastal lagoons of the east coast of South America is presented. However, researchers of Uruguay, Argentina, and Brazil should make an effort to bring together the large amount of regional papers and publish a thorough and comprehensive review.

Study area: climate, geology, limnology, and vegetation

Uruguay is located on the east coast of South America at the lower section of the La Plata and Merín basins (Figure 1). The climate is temperate/subtropical with mean seasonal temperatures of 17°C in spring, 25°C in summer, 18°C in autumn, and 12°C in winter. However, extreme temperatures can be attained during summer (~40°C) and winter (−5°C). The prevailing winds are from the East and Northeast (warm/wet), and from the South (cool/dry). The mean historical rainfall in the southern region is ~1,100 mm year^{−1}, whereas in the north-western is ca. ~1,300 mm year^{−1}. Mean humidity is 75%, and mean cloudiness is 60%.

The geological setting consists of Cretassic, Devonian, Gondwanic, Jurassic, Mesozoic, and Cenozoic sediments, and the La Plata River and East basements. The southern region of the country corresponds to the Uruguayo-Riograndense Shield, upon which Pleistocene and Holocene formations (Libertad, Villa Dolores, and Villa Soriano) were deposited (López-Laborde et al., 2000). Thus, Holocene deposits of Uruguay are best represented in the lagoons and the wetlands. The most abundant limnological systems of the country are large rivers and a network of many small rivers and streams/creeks, which limnological state has been reviewed by Conde and Sommaruga (1999).

The coastal zone is 680 km long, from which 542 km corresponds to the La Plata River and 228 km to the ocean. The lagoons are all shallow systems (i.e., ~5 m deep) but differ in the type of connection to the ocean, elevation, and distance from the sea. Therefore, they exhibit different limnological conditions (Table 1). Both Lake Blanca and Sauce Lagoon are a drinking water source for local residents, fisheries activities are undertaken in Rocha and Castillos Lagoons, while the catchment of Negra Lagoon is used for rice fields. In addition, since the 1940s, extensive cattle/sheep grazing, forestry of both *Eucalyptus* sp. and *Pinus pinaster*, removal and

fertilization of soils, as well as construction of dams, led to several eutrophication episodes (Rodríguez, 2006; García-Rodríguez et al., 2002b).

The lagoon catchments correspond to the Pampa phytogeographic province which is characterized by slight elevations and valleys and consists mainly of wetlands, meadows, riparian forests, and palm forests of *Butia capitata*. The common wetland vegetation in southern Uruguay is represented by the genera *Alternanthera*, *Azolla*, *Bacopa*, *Cabomba*, *Ceratophyllum*, *Cyperus*, *Egeria*, *Eichornia*, *Enhydra*, *Glyceria*, *Hydrocotyle*, *Leersia*, *Lemna*, *Limnobia*, *Ludwigia*, *Luziola*, *Mikania*, *Myriophyllum*, *Oxycarum*, *Pistia*, *Polygonum*, *Potamogeton*, *Rynchospora*, *Ricciocarpus*, *Schoenoplectus*, *Scirpus*, *Solanum*, *Spirodela*, *Typha*, *Utricularia*, *Wolffiella*, and *Zizaniopsis* among others (Alonso, 1997). The grass vegetation of the meadows is characterized by *Andropogon*, *Axonopus*, *Panicum*, *Paspalum*, *Schizachyrium*, *Bothriochloa*, *Stipa*, *Piptochaetium*, and *Aristida*. Riparian forests are restricted to the littoral of small streams and are represented by *Lithraea brasiliensis*, *Schinus longifolius*, *Sapium* spp., *Sebastiania* spp., *Blepharocalyx salicifolius*, *Celtis* spp., *Syagrus romanzoffiana* (Iriarte, 2006).

Holocene sea-level changes

The long-term development of the coastal environments depends on sea-level change, as the geomorphology and limnology of coastal lagoons are influenced by oceanographic processes. Lambeck et al. (2002) have shown that glacial/interglacial climate conditions over the past 3 Ma

have been characterized by an immense transfer of water from the ice sheets. About 50 million km³ of ice melted from ice caps, raising global sea level by ~130 m. Such changes in sea level are part of interactions between the atmosphere, oceans, ice sheets, and solid earth. The trigger for the sea-level fluctuations lies with changes in insolation, astronomical forcing, and internal feedback mechanisms such as ocean circulation or tectonics.

During the past three decades, increasing evidence on sea-level variation in the east coast of South America has been published (Isla, 1989; Martin and Suguio, 1992; Angulo and Lessa, 1997; Isla, 1998; Angulo et al., 1999; Lessa et al., 2000; Bezerra et al., 2003; Cavallotto et al., 2004; Angulo et al., 2006). Although there are certain differences between the models (Figure 2), they all propose a transgressive phase after Last Glacial Maximum; sea level was first overtaken ~7,000 year BP, maximum sea level was achieved between 6,000 and 5,200 year BP, and then there was a regressive phase until contemporary times (Figure 2). In Brazil, two submergence/emergence events (~4,000–3,900 and 2,800–2,700 year BP) were recorded by some authors (Figure 2), but others did not observe such sea-level trends. In eastern Argentina, the above two emergence/submergence events were not observed either (Isla, 1998; Cavallotto et al., 2004). The Brazilian models propose that Holocene sea level achieved a maximum between 4 and 5 m AMSL, while in Argentina, Isla (1998) proposed that maximum sea level was 4 m AMSL, whereas Cavallotto et al. (2004) observed a maximum sea level of 6.5 m AMSL. The variability in Holocene sea-level changes over different

Regional models of sea level change (m)

South America, Holocene Coastal Lagoons, Figure 2 The regional models of Holocene sea-level change for the east coast of South America.

localities may be a consequence of glacial eustasy, geoidal eustasy, tectonics, and hydrometeorological changes such as storms (Bezerra et al., 2003; Cavallotto et al., 2004). Therefore, corrections should be introduced into the curves to obtain eustatic sea-level information for different localities. Although some of the variables are relatively well known (i.e., storms), little data are available on neotectonics and geoid effects. Therefore, Cavallotto et al. (2004) concluded that it is still not convenient to apply corrections until reliable information is available. As a result, sea-level fluctuations should be considered as relative and overestimated. Even though the data on sea-level changes are not completely exact, the models

still provide interesting trends to which the Holocene paleolimnology of the coastal lagoons can be compared. However, the long-term history of coastal lagoons also depends on other factors, as the paleoenvironmental conditions of the coastal zone were shown to be a consequence of the links between sea-level changes and climate (Lambeck et al., 2002).

Late Pleistocene and Holocene paleoclimate

Information on climate change is particularly important for developing countries, such as those of South America, as they are particularly vulnerable to climatic changes (e.g., El Niño Southern Oscillations, Ravindranath and

Sathaye, 2002). Instrumental data on climatic variability are only available since the beginning of the twentieth century. However, these records are too short to detect decade-to-century or millennia climate variability (Xiong and Palmer, 2000). Thus, to hindcast Pleistocene/Holocene climate changes, proxy data derived from geological, chemical, or biological records are needed.

The Late Pleistocene and Holocene paleoclimatic trends in the Pampa phytogeographic region were characterized by a transition from cool and dry to temperate/subtropical and humid. During the Holocene, a high variability in climatic conditions was observed by

different authors, as different climatic trends can be found in the literature (Figure 3).

Kröhling and Iriondo (1999), Iriondo (1999), and Iriondo and García (1993) proposed the following climatic episodes for the Argentinean Pampa: (1) 18,000–8,500 year BP, Arid and cool; (2) 8,500–3,500 year BP, humid subtropical; (3) 3,500–1,000 year BP, dry subtropical; (4) LIA, between 800 and 200 year BP; (5) Present climate, nineteenth and twentieth century, subtropical humid. However, Mancini et al. (2005) reviewed 42 published records of pollen in the Pampa region and inferred the occurrence of dry episode about 6,000 year BP. In addition by ~4,000 year BP, a dry

South America, Holocene Coastal Lagoons, Figure 3 Late Pleistocene and Holocene paleoclimatic trends for the Pampa region.

Pampa with occurrence of halophytic vegetation was still observed. Prieto et al. (2004) and Prieto (2000) inferred cool dry conditions from late Pleistocene to 7,000 year BP, when a shift to subhumid–dry climate was observed, but climate became even dryer during the late Holocene.

Paleoclimatic data from Uruguay indicate differences with not only the Argentinean Pampa but also intrinsic variability between localities of the country (Figure 3). For example, Bracco et al. (2005a), Iriarte (2006), del Puerto et al. (2006), and Inda et al. (2006) observed the occurrence of both dry and humid conditions during early Holocene. Such discrepancies could be explained because of the high variability in climatic conditions. However, the late Holocene appears to be characterized by the onset of warm, humid, and more stable conditions (Figure 3).

In Brazil, authors reported paleoclimatic trends that further suggest high climatic variability within the Pampa phytogeographic region during mid-Holocene (Hilgert-Cordeiro and Lorscheitter, 1994; Behling, 1997; Behling, 1998; Behling, 2002; Behling et al., 2004). For instance, Behling et al. (2004) studied a high-resolution pollen record from southern Brazil, and Behling (2002) reviewed 14 pollen records from southern Brazil. They proposed cool and dry conditions for the late Pleistocene, warm and dry for the early and mid-Holocene, while conditions similar to the modern climate were established after ~4,300 year BP, and especially after 1,500–1,000 year BP (Figure 3).

Most of the above literature deals with pollen and opal phytoliths as proxies for climate. Thus, they also provide valuable information on the Holocene vegetation of the terrestrial environments and the catchments of the coastal aquatic systems. The dry and cool climatic events (early Holocene) were characterized by dominance of C3 grasslands (i.e., pooid phytoliths) and halophytic vegetation such as Asteraceae, Amaranthaceae, and Chenopodiaceae (Bracco et al., 2005a; Stutz, 2006; Iriarte, 2006; del Puerto et al., 2008). During the more humid episodes of the late Holocene, increases in wetland taxa of Cyperaceae were recorded with concomitant increases in C4 grasslands (i.e., panicoid and chloridoid phytoliths). The relationship between paleoenvironmental conditions of coastal systems and pollen associations was tested by Stutz and Prieto (2003), using recent samples in the Pampa region (Buenos Aires, Argentina). They developed a model of vegetation distribution in relation to the environmental conditions. Such a model has shown that the plant associations exhibited distinct pollen assemblages that conform the paleoclimatic trends: (1) the psammophytic community, characterized by Poaceae, Cyperaceae, and maximum values of psammophytic types; (2) the halophytic community, characterized by maximum values of Chenopodiaceae; and (3) the freshwater community, represented by maximum values of both Cyperaceae and hydrophytic types and by Poaceae.

All the papers on paleoclimatic data discussed here agree with cool and arid conditions for Late Pleistocene. The Holocene (and especially early to mid-Holocene)

was characterized by high variability in climatic conditions, while most authors observed the onset of humid conditions during the late Holocene.

Holocene paleolimnology of coastal lagoons

The limnology of aquatic systems is strongly related to the climatic/seasonal conditions. In the case of coastal systems, marine intrusions (e.g., storms, tidal influence) also moderate the limnological conditions (Hilmer and Bate, 1990; Conde et al., 1999; Conde et al., 2000; Conde et al., 2002; Hassan et al., 2006). In this sense, Holocene sea-level changes play a major role in influencing the paleolimnological conditions as well (Sprechmann, 1978; Oschmann et al., 1999; García-Rodríguez et al., 2001; García-Rodríguez et al., 2002b; García Rodríguez and Witkowski, 2003; Espinosa et al., 2003; García-Rodríguez et al., 2004a; García-Rodríguez et al., 2004b; García-Rodríguez et al., 2004c; Stutz et al., 2006). Thus, the paleoclimatic, paleolimnological, and paleoceanographic interactions are thought to determine the sedimentary, chemical, and biological structure of coastal lagoons.

Sedimentary aspects

The sediment deposition/resuspension in coastal lagoons is related to the energy of the physical processes of the water column (i.e., turbulence, tidal currents, wave action). In those areas where high-energy physical processes occur, coarse sediment particles are observed (i.e., sand). On the other hand, low-energy environments are dominated by fine sediment particles (i.e., silt, clay, mud) (Isla and Espinosa, 1995; Bersezio et al., 1999; Kjær, 1999; Klingbeil et al., 1999; Wang and Ke, 1999; Stewart et al., 2000). Wang and Ke (1999) undertook a detailed study in the coastal zone in China and demonstrated that there is a close relationship between the energy and the sediment composition. They observed that the supratidal section was dominated by silt/clay, the intertidal section by silt/sand, while the beach was dominated by sand. A similar sediment gradient can also be found in Uruguay (e.g., Rocha Lagoon) (Corbellini, 1983; Sommaruga and Conde, 1990) or Argentina (e.g., Mar Chiquita Lagoon) (Isla and Espinosa, 1995). With this in mind, the different lithological units of a sediment core reflect the environment in which they were deposited. Therefore, those lithological units dominated by sand will represent high-energy environments (e.g., beaches), while those dominated by silt/clay will indicate low-energy environments (e.g., lacustrine systems).

The eleven sediment cores retrieved from the five coastal water bodies in southern Uruguay (Figure 1) showed a similar lithological composition, which can be summarized as follows. During the first Holocene marine transgression (i.e., ~7,000–4,000 year BP), high relative percentages of sandy sediments were observed (Figure 4). After the regressive phase until ~2,000 year BP, when sea level was ~2 m AMSL, increases in sand/silt sediments were recorded. During the last stage of the

South America, Holocene Coastal Lagoons, Figure 4 Generalized model of paleolimnological changes in the coastal lagoons of southern Uruguay during the Holocene. For detailed information, see García-Rodríguez (2006); Inda et al. (2006); del Puerto et al. (2006); García-Rodríguez et al. (2002b); García Rodríguez and Witkowski, (2003); García-Rodríguez et al. (2004a); García-Rodríguez et al. (2004b); García-Rodríguez et al. (2004c); Bracco et al. (2005a).

regressive phase (i.e., after 2,000 year BP) as sea level continued to decrease, dominance of silt/sand was observed (García-Rodríguez et al., 2001; García-Rodríguez et al., 2002b; García Rodríguez and Witkowski, 2003; García-Rodríguez et al., 2004a; García-Rodríguez et al., 2004b; García-Rodríguez et al., 2004c). Similar lithological composition of sediment cores was recorded in Mar Chiquita Lagoon and Hinojales Lagoon in Buenos Aires Province, Argentina (Stutz et al., 2006), but also in Los Patos Lagoon in Rio Grande do Sul, Brazil (Oschmann et al., 1999, Figure 1). The above facts indicate that there is a strong relationship between lithology and sea-level changes, and therefore, the paleosalinity of coastal lagoons (Figure 4). In addition, the lithological units of the sediment cores of the coastal lagoons also contain mollusk shells which corroborate the relationship between lithology and paleosalinity (Oschmann et al.,

1999; García-Rodríguez et al., 2001; García-Rodríguez et al., 2002b; García Rodríguez and Witkowski, 2003; Espinosa et al., 2003; García-Rodríguez et al., 2004a; García-Rodríguez et al., 2004b; García-Rodríguez et al., 2004c). That is, during the first Holocene marine transgression, high abundances of entire/articulated remains of marine/brackish mollusks were observed. The most representative species with their optimum salinity ranges (Sprechmann, 1978; Aguirre and Urrutia, 2002; Bracco et al., 2005b) included: *Heleobia australis* (0.5–6‰), *Erodona mactroides* (10–18‰), *Tagelus plebeius* (0.5–29‰) and *Pitar rostratus* (18–30‰). After ~2,000 year BP (i.e., during the last stages of the regression), as salinity levels decreased, a reduced content of entire articulated mollusk shells were observed. Similar data on mollusk have been reported for both Los Patos Lagoon and Mar Chiquita Lagoon (Oschmann et al., 1999; Stutz et al., 2006, Figure 1).

Chemical aspects

Knowledge on Holocene trophic state of coastal lagoons is very important, as it provides with information on both eutrophication and oligotrophication episodes. The trophic state index is often expressed as total carbon, total nitrogen, and total phosphorus content. In addition to this, the C/N ratio allows to discern between different sources of organic matter (i.e., terrestrial >30, macrophytes ~12, plankton ~7, bacteria ~4) (Müller and Mathesius, 1999; Kaushal and Binford, 1999; Meyers and Lallier-Vergès, 1999), and thus, a precise balance on the relative importance of autochthonous and allochthonous energy inputs can be determined. Since coastal lagoons are subject to many external inputs, because of the occurrence of erosion processes in the coastal zone, the composition of the organic matter in a sedimentary profile is a very useful tool to reconstruct such processes.

Both transgressions and regressions appear to be the most important factors influencing not only the salinity but also the trophic state of coastal lagoons (García-Rodríguez et al., 2001; García-Rodríguez et al., 2002b; García Rodríguez and Witkowski, 2003; García-Rodríguez et al., 2004a; García-Rodríguez et al., 2004b; García-Rodríguez et al., 2004c; Bracco et al., 2005a). During Holocene transgressive episodes, relatively low trophic states were inferred for the coastal lagoons of southern Uruguay, as low organic matter, total carbon, total nitrogen, and total phosphorus were recorded. This is because the trophic state of inland systems is usually higher than that of the open ocean because of both external inputs as well as internal loading (Margalef, 1983). On the other hand, during regressive episodes, higher content of nutrients and organic matter were recorded because of the increased runoff/erosion (as C/N values of ~30 indicated inputs of terrestrial components) (García-Rodríguez et al., 2004a; García-Rodríguez et al., 2004b), while regressions took place. Therefore, an inverse relationship between trophic state and sea-level variation (and paleosalinity levels) was inferred for the Holocene coastal lagoons of the east coast of South America. Moreover, Inda et al. (2006) determined that during the first Holocene marine transgression (i.e., 7,000–4,000 year BP), both higher frequency and lower amplitude sea-level oscillations than those reported in the regional models of sea-level change also moderated the trophic state of Rocha Lagoon (Figure 1). That is, during marine/brackish stages, decreases in trophic state were recorded. On the other hand, low trophic state was associated to brackish/freshwater episodes.

During the final stages of the Holocene regression (i.e., after 1,500 year BP), some of the coastal lagoons became separate from the ocean (e.g., Lake Blanca [del Puerto et al., 2006; García-Rodríguez et al., 2004a] and Negra Lagoon [Bracco et al., 2005a]), until the onset of freshwater systems. During the separation process, because of the combined effect of a regressive phase and either a climatic amelioration or deterioration, changes in

trophic state were observed (García-Rodríguez et al., 2004a; del Puerto et al., 2006). In the case of Lake Blanca, the separation process began by the little ice age (LIA, by ~800–200 year BP) (Iriondo and García, 1993). Both nutrient depletion and a decrease in trophic state (indicated with a dashed line in Figure 4) were observed during such a climatic deterioration. Negra Lagoon became separate from the ocean by ~1,700 year BP (Bracco et al., 2005a) at which time a climatic amelioration was inferred (Figure 3). Consequently, eutrophication intensified (depicted with a solid line in Figure 4), as the highest organic matter contents in the history of the water body were measured. Thus, the trophic state of coastal systems during the separation process from the ocean appears to be controlled by both climate and sea-level variation.

Biological aspects

The microfossils deposited in sedimentary profiles are excellent indicators of the paleoenvironmental conditions. Among them, diatoms have been often utilized in paleoecological studies of coastal environments, as the silica structures are resilient to paleoenvironmental degradation (Frenguelli, 1941; Frenguelli, 1945; Müller-Melchers, 1945; Maidana, 1994; Witkowski, 1994; Denys and de Wolf, 1999; Metzeltin and García Rodríguez, 2003; Espinosa et al., 2003; Hassan et al., 2006). In addition to diatoms, other silica remains, such as chrysophyte cysts, have been often utilized in paleoenvironmental reconstructions as well (Smol, 1985; Cumming et al., 1993; Lotter et al., 1997, 1998; Karst and Smol, 2000; Forrest et al., 2002). Both diatoms and chrysophyte cysts are very good indicators of several environmental variables. However, in the case of Holocene coastal lagoons, they were shown to reliably mirror the paleosalinity changes caused by sea-level variations (García Rodríguez and Witkowski, 2003; Espinosa et al., 2003; García-Rodríguez et al., 2004a; García-Rodríguez et al., 2004b; García-Rodríguez et al., 2004c; Hassan et al., 2006; Vilanova et al., 2006). In addition to this, the ratio of chrysophyte cysts to diatoms [first introduced by Smol (1985) to track trophic state changes in freshwater systems] was shown to be a reliable and simple tool to infer paleosalinity changes in coastal lagoons (García-Rodríguez, 2006). Since chrysophytes are rarely found in marine environments (Duff et al., 1995; Rull and Vegas-Vilarrúbia, 2000), their relative abundance in coastal systems changes following salinity levels (i.e., ratios of chrysophyte cysts to diatoms increase with a decrease in salinity). Thus, by tracking changes in this simple ratio in a sediment core, shifts in paleosalinities could be reconstructed.

The major environmental change during the early Holocene in the east coast of South America was the occurrence of the marine transgression (Figure 3). Consequently, there was a transition from terrestrial systems to the formation of coastal lagoons because of the high sea-level stand (Figure 3). During this stage, aquatic systems exhibited marine/brackish conditions as indicated by high

abundances of marine/brackish diatoms (Figure 4). In addition, very low values or even absence of chrysophyte cysts were detected (García-Rodríguez, 2006). As the Holocene regressive phase started after ~5,000 year BP, decreases in salinity levels were detected, thus leading to the establishment of brackish/freshwater systems by ~2,000 year BP (Figure 4). Diatom flora was shown to be dominated by brackish/freshwater species (Figure 4), and concomitant increases in chrysophyte cysts were observed (García-Rodríguez, 2006).

The time and magnitude of the transition from marine/brackish to brackish/freshwater was related to the elevation, distance from the shore (see Table 1), possible river/steam freshwater discharges, morphometry, and catchment geomorphology. For instance, Rocha Lagoon (Figure 1) is presently separated from the sea by a sand bar that opens several times a year if water level increases above ~1.3 m (Conde and Sommaruga, 1999). Thus, this water body is classified as a marine/brackish system, although freshwater pulses occur during the winter. For this reason, the water body never achieved a full brackish/freshwater stage during the Holocene. Lake Blanca and Negra Lagoon are respectively elevated 4 m and 8 m AMSL, and they do not open to the sea (Table 1). Both systems exhibited marine/brackish conditions during the early Holocene, brackish/freshwater during the mid-Holocene, but a full freshwater system was only established after ~1,000 year BP, when sea level was about +1 m AMSL (García-Rodríguez et al., 2004a; Bracco et al., 2005a). During the full freshwater stage, dominance of freshwater diatoms was recorded (Figure 4).

Palynological studies provide information not only on the macrophyte associations but also on the nonsiliceous microalgae, which can be ultimately related to the paleosalinity changes. Stutz et al. (2006) reconstructed the Holocene pollen associations of Mar Chiquita Lagoon (Figure 1) and observed that prior to 5,000 year BP, both psammophytic/halophytic associations developed on extensive sandy flats. Between 4,000 and 2,500 year BP, during a period of sea-level stabilization, similar halophytic communities were observed, but after 2,500 year BP, as sea level continued to decrease, freshwater associations were established. In addition, freshwater microalgae (*Scenedesmus*, *Zignemataceae*, *Botryococcus*, and *Gloetrichia*) increased relative abundances after ~2,500 year BP, thus indicating decreases in paleosalinities. del Puerto et al. (2008) observed similar changes in pollen associations in Negra Lagoon (Figure 1), which, combined with a previous record of diatoms and chrysophyte cysts, provided an outstanding record of paleoenvironmental information. This highlights that studies combining both siliceous and nonsiliceous microalgae represent an exceptional and relatively cheap approach for paleoenvironmental studies.

Human impacts in recent times

The Anthropocene is the most recent geological epoch. Smol et al. (2005) analyzed 55 sediment cores from lakes

South America, Holocene Coastal Lagoons, Figure 5 Changes in organic matter content in sediment cores taken from two drinking water sources. For location of both systems, see Figure 1. Data from Lake Blanca reproduced with kind permission of Springer Science and Business Media (García-Rodríguez et al., 2002b, Figure 3).

in the circumpolar Arctic. They observed that because of climate warming through lengthening of the summer growing season and associated limnological changes, a widespread species changes in algae and invertebrate associations took place since ~1850 AD. Thus, the Anthropocene is characterized by the human modification of biogeochemical cycles and climate. Anthropogenic changes in the coastal systems of Uruguay are best represented in Sauce Lagoon and Lake Blanca. Both systems are a drinking water source for local residents (Table 1). The paleolimnological evidence indicates that once the human activities started, eutrophication episodes were observed (Figure 5). Sauce Lagoon (elevation 7 m, distance from the sea 2 km, Table 1) was still connected to the sea during late Holocene (Rodríguez, 2006), and only after the construction of a dam in 1944,

a freshwater system was established. The system became a reservoir and the residence time increased. Concomitant increases in organic matter and nutrients, together with changes in diatom composition, were recorded (Rodríguez et al., 2006). In Lake Blanca, forestry activities in the catchment by ~1960 AD (García-Rodríguez et al., 2002b) led to increased phosphorus inputs and organic matter content (Figure 5). Therefore, after the drinking water facilities became operative, eutrophication intensified in both cases. In addition, microalgae blooms and problems associated to the odor and taste of the water were reported by the local residents. In this sense, paleolimnological techniques provided important historical information to help us understand the eutrophication process after human impacts. Such information would have been otherwise unobtainable, as limnology as a science in Uruguay dates only from early 1980s. Thus, particularly in developing countries, paleolimnological studies are necessary to provide baseline limnological data and assist managers and decision makers toward a sustainable use of our aquatic systems.

SOUTH AMERICA, LAKES REVIEW

Rhodes W. Fairbridge (Deceased), Lars Bengtsson¹
¹Department of Water Resources Engineering, Lund University, Lund, Sweden

Introduction

With an area of about 17,826,530 km² (6,878,521 mi²), South America extends from about 12°N to 54°S, and 35°W to 81°W. On the W., it is bordered by the Pacific and on the E., by the Atlantic, with the Caribbean Sea to the N. It is separated in the S. from Antarctica by the Drake Strait. To the N., it is linked to Central America by the Isthmus of Panama. Its highest mountain is Cerro Aconcagua in Argentina (6,960 m; 22,834 ft). The continent is divided by the equator which runs from Ecuador through Brazil to the mouth of the Amazon.

Geologically, the continent is part of the pre-plate-tectonic breakup of Gondwanaland which began about 245 M years ago with fractures along the NE and eastern margins, separating it from West Africa, associated with subduction along the Pacific margin that created the 9,000-km-long Andean orogenic and volcanic belts. This Andean belt swings around in the N to face the Caribbean which had a complex history of convergence and divergence.

The lakes of South America reflect this geotectonic history, as well as its meteorological diversity, from the tropics to the subarctic and from sea level to the endorheic region of the Andean “altiplano” (high plateau, over 2,800 m elevation), which covers 220,000 km². More than 99.8% of the exorheic drainage is into the Atlantic (Figure 1).

Classification

South America’s lakes may be categorized generically as follows:

(a) Structural:

For example, *Lake Titicaca*, 8,110 km² (3,130 mi²), partly in Peru, partly in Bolivia, is at

South America, Lakes Review, Figure 1 Distribution of lakes in South America. 1, Fagnano; 2, Argentino; 3, Viedma; 4, San Martín; 5, Buenos Aires; 6, Colhue Huapi; 7, O'Higgins; 8, Nahuel Huapi; 9, Llanquihue; 10, Musters; 11, General Carrera; 12, Mar Chiquita; 13, Mirim; 14, Patos; 15, Yacyreth; 16, Posadas; 17, Taipul; 18, Poopo; 19, Titicaca; 20, Peru; 21, Tucurui; 22, Suriname; 23, Maracaibo; 24, Alberto Lleras.

3,812 m elevation; freshwater; fed by snow-melt rivers from the Andes.

Lake Poopó (Pampa Aullagas), in the central plateau, is highly saline, being in a rain-shadow area and having no outlet. Other "salars" (e.g., Salar de

Uyuni, S. de Coipasa) and salt lakes are numerous in the "puna" or high Plateau (nearly 4,000 m).

Lake Lauricochoa, Peru, about 6 km long, feeding into the Marañón R., and hence the Amazon, one of its headwaters.

Lake Mar Chiquita, Argentina, about 75 km long, seasonally to 150 km (fed by Rio Dulce from the central Andes).

Lake Musters and Lake Colhué Huapi, in central Patagonia, are fed by waters from the Eastern Andes, together with a large peppering of smaller lakes throughout the Pampas region of Patagonia that appear to be fed by artesian sources.

Laguna Ginebra, in northern Bolivia, together with a large number of smaller bodies and swamps of the Llanos de Mojos, appear also along the eastern Andean foothills.

(b) *Volcanic*:

Crater lakes are of necessity small but fairly numerous in the low-frequency eruptive centers of the Andes. Certain instances are at very high elevations and are capped by perennial snow. In the unusual event of renewed activity, catastrophic lahars (mudflows) are initiated.

(c) *Glacial*:

For example, Sea-level outlet glaciers form small lakes due to the block of meltwaters on the Pacific side of Patagonia (in Chile); several areas are set aside as national parks.

The Pleistocene glaciated valleys of the Atlantic (Argentine) side, e.g., Lake Nahuel Huapi (Argentina, about 65 km long, a national reserve). Several lakes overlap the Chilean border (and hence have two names), e.g., L. General Carrera/L. Buenos Aires, L. O'Higgins/L. San Martin. Lago Viedma is entirely on the Atlantic side, as is the L. Argentine (both the latter are part of a national glacier park).

(d) *Coastal embayment*, tectonically modified:

For example, *Lake Maracaibo*, 560 mi², a brackish, mixed marine and freshwater depression.

Coastal tectonics is also a factor farther W. in Bolivia, producing, e.g., the Cienaga Grande ("Big Lagoon") and others around Cartagena and Barranquilla (mouth of Magdalena R.). Farther upstream, a subsidence area has created a large number of smaller lagoons and swamps.

(e) *Coastal lagoons*, barred by littoral drift and dunes:

For example, Lagoa dos Patos and L. Mirim (Rio Grande do Sul, Brazil); also at Cabo Frio (L. de Afaruama), and Cabo de São Thomé (L. Feid). More are clustered at the delta of the Rio Doce where cyclic sedimentation has built up a sequence of beach ridges that serve to isolate the lakes.

(f) *Amazonian seasonal lakes*: Maximum rate of discharge about 100×10^3 m³/s.

Much of the Amazon valley becomes a series of major ephemeral lakes during the snow-melt season in the Andes (southern summer). Prior to the plate-tectonic separation from West Africa, the Amazon flowed westward, a major drainage reversal feature.

(g) *Dams and reservoirs*:

Two of the world's highest dams are in South America, both in Columbia – the Alberto Lleras C.

(243 m) and La Esmeralda (237 m) – and three of the world's largest embankment dams – Tucuui in Brazil (85,200 m³), Yacireta in Argentina (81,000 m³), and Guri in Venezuela (70,000 m³). Guri retains the seventh largest reservoir in the world (135,000 million cubic meters). Fifteenth largest is the Serra da Mesa reservoir in Brazil with 54,400 million cubic meters (according to the "World Almanac" for 2003). ["Represa" is Portuguese for reservoir; "embalse" in Spanish.]

Suriname, the former Dutch colony, has several moderate-sized reservoirs, one having the distinction of being named after a professor of Hydrology: "Professor van Blommerstein Meer."

There is an *International Commission on Large Dams*, which also lists the world's largest capacity hydroelectric dams, as follows:

- #3. Itaipu (on Paraná R. near Iguassu Falls, Brazil/Paraguay, 7,400 MW; potential, 13,320 MW)
- #5. Guri (Raoul Leoni, Venezuela, 10,300 MW)
- #6. Tucurui (Brazil, 2,640 MW; potential, 7,260 MW)
- #8. Corpus Posadas (on Paraná R. above Apipé Rapids; potential, 6,000 MW)
- #12. Xingo (on the Xingu, a major tributary of the Amazon, Brazil, 3,012 MW potential, 5,020 MW)
- #19. Paulo Alfonso L. (Brazil, 1,524 MW; potential 3,409 MW)
- #20. Pati (Brazil; potential, 3,500 MW)
- #21. Ilha Salteira (Brazil, 3,200 MW)
- #22. Chapecón (Brazil; potential, 3,000 MW)

Conclusion

South America, after Australia, has the fewest and least capacity of the world's lakes, in proportion to its area, although it has the world's largest river, the Amazon (length about 6,400 km; annual discharge to Atlantic Ocean: 6,930 km³). Most of the drainage is exorheic, very little endorheic, or arheic.

It is too soon to measure the effects of major deforestation and uncontrolled logging on sedimentation rates and the consequent filling of South American lakes and reservoirs. However, the red color of the eroded soils is readily apparent from the air, e.g., below the new highway crossings on Amazonian rivers and on other tropical rivers out into the Atlantic (personal observations: RWF).

STRATIFICATION AND MIXING IN TROPICAL AFRICAN LAKES

Sally MacIntyre

Department of Ecology, Evolution and Marine Biology,
University of California, Santa Barbara, CA, USA

Introduction

The lakes in tropical eastern Africa are concentrated in the Eastern and Western Rift Valleys. The Eastern Rift Valley, which extends from northern Tanzania into the Danakil Depression in Ethiopia, is semiarid. The majority of the lakes within it are closed basin lakes, that is, they receive water from incoming rivers and precipitation but have no outlet. They tend to be salty, sometimes saltier than seawater, due to evaporative concentration of their waters. The lakes which are near the rift boundaries are long, narrow, and tens of meters deep, whereas those away from the boundaries are primarily pans that are tens of kilometers squared in surface area and generally a few meters deep. A number of small crater lakes formed when magma, close to the Earth's surface, superheated the overlying groundwater causing an explosion. Lakes in the Western Rift Valley are exposed to a wetter climate and many have outlets and are fresh. The larger ones are graben lakes, that is, lakes created as the continental plates separated. Due to their large size, at least 200-km long and 50–1,500-m deep, they are called the African Great Lakes. Lake Tanganyika is the largest of these lakes, 650-km long and over 1,000-m deep. Only Lake Baikal in Siberia, also a graben lake, is deeper. Lake Turkana is the only lake in the Eastern Rift Valley which is classified as a Great Lake. Due to volcanism in the area, crater lakes are numerous with distinctive chemical compositions. Lake Kivu is in part fed by subterranean springs with high concentrations of CO₂. Consequently, even though it has an outlet, it is chemically stratified. Lake Victoria, the second largest lake by surface area on Earth, is located between the two rift valleys. Formed by the combination of uplift and subsidence, at 80-m deep it is the shallowest of the African Great Lakes. Its climate is complex, with the eastern side arid and the western and northern sides receiving high precipitation. The stratification and mixing of lakes in tropical Africa are influenced by their geological setting particularly as it influences their depth.

The physical properties of water at warm temperatures provide another important influence. That is, at temperatures above 20°C, temperature differences of a degree or two cause density differences which are larger than would be found for temperature differences of 5°C or 6°C at cooler temperatures. Thus, warming of the upper waters in the day causes appreciable increases in density. Night-time cooling, however, can erase the density stratification. The minimum temperatures in lakes at all latitudes are set, in part, by minimum air temperatures, which are warm and with minimal annual variation in the tropics. For the lakes closest to the equator, minimum air temperatures are only

a few degrees cooler than maxima and the temperature gradient between surface and bottom waters is small. Due to the warm surface temperatures, evaporation rates are high. As a result of the high evaporation rates, mixing due to wind or cooling can extend to deeper depths than in lakes outside the tropics, and conditions are less favorable for the establishment of seasonal stratification such as that found in temperate and arctic lakes. In consequence, the shallow lakes exposed to wind tend to stratify and mix to the bottom on a diel basis and are classified as "polymictic." For seasonal stratification to develop, the lakes must be tens of meters deep or within craters. On the other hand, the very deep lakes, Malawi, Tanganyika, and Kivu, are meromictic, that is, they do not mix completely each year or for many years. Some of the small crater lakes are also meromictic, but due to their shallower depths, may mix during periods of drought which cause reductions in their depth and any chemical stratification.

Distance from the equator causes between lake variability in mixing dynamics for lakes of similar size and depth. Variability in solar radiation and in maximum and minimum air temperatures increases with distance from the equator. In addition, seasonality is influenced by the movement of the Intertropical Convergence Zone (ITCZ). Rainy seasons occur when the ITCZ passes over a lake, although there may be lags, with tropical lakes farthest from the equator having one rainy season and those closer having two, one as it moves north and a second as it moves south. The movement of the ITCZ determines the attributes of air masses which are advected over the lakes. For instance, when the ITCZ is over a lake, the air may be humid. As it moves north in the southern hemisphere or south in the northern hemisphere, cool dry air sweeps across the lakes and wind speeds tend to be higher. The deeper lakes tend to stratify during the rainy season and mixing is deepest during the dry seasons. Due to this suite of factors, the variability in lake surface temperatures increases with distance from the equator and the potential for seasonal stratification further increases.

In the following, the first section reviews drivers of vertical mixing and processes which cause horizontal circulation. This section is followed by a description of the mixing dynamics in shallow, moderately deep, and deep tropical lakes and of unusual mixing dynamics caused by stabilizing inflows of groundwaters enriched in dissolved gases. Reviews of studies of mixing dynamics of tropical lakes can be found in Beadle (1981); Talling and Lemoalle (1998); and Spigel and Coulter (1996).

Stratification and mixing of lakes

As background, this section provides a brief description of the various processes causing mixing and horizontal transport in lakes, the meteorological drivers for these processes, and dimensionless indices which enable patterns to be identified. Convection, induced by heat loss and wind, causes the upper mixed layer to mix and deepen. Convection leads to the well-known overturning of many temperate lakes in the fall and tropical lakes during dry,

windy periods and is an important determinant of the depth of the mixed layer when lakes are seasonally stratified. The associated turbulence affects the light climate of phytoplankton by circulating them in a light gradient, and nutrient supply and gas flux via entrainment of water from below the mixed layer. Convection can also induce horizontal exchanges in lakes by processes known as differential heating, cooling, or wind mixing. These processes can be important for exchanges between the littoral and pelagic zone in small, sheltered lakes as well as larger lakes. These flows are density-driven flows, with increased heating in shallow regions of a lake causing surface overflows, and increased cooling in shallow regions causing gravity currents which sink until they reach water of similar density, or the bottom, and then flow offshore (Monismith et al., 1990). A related process, in which near continuous heating occurs on one side of an embayment or lake, can cause horizontal convection cells which persist for extended periods. Recent observations and modeling indicate it causes lake-wide transports in Lake Tanganyika (Verburg et al., 2011). Convective processes are quantified based on the amount of heating or cooling at a lake's surface. Evaporation is a primary driver, although cloud-free skies and concomitant increases in net long wave radiation are also important. The extent of convective mixing or circulation depends on air and surface water temperature, wind, and relative humidity. Thus, mixing depths can be deep in tropical lakes with their warm surface water temperatures, and nocturnal cooling can be sufficient to trigger inshore-offshore exchange by gravity currents. River inflows can be warmer or cooler than the receiving lake waters and initially flow over a lake's surface or penetrate below the surface, with the subsequent within-lake-mixing processes determining the extent of mixture of river and lake waters. The differences in molecular diffusivity of heat and salts can also cause vertical exchange and sometimes horizontal convective cells in lakes in which both temperature and conductivity increase with depth. This process is called "double diffusive convection" and is found in deep, chemically stratified lakes.

Upwelling of the thermocline and the breaking of nonlinear internal waves are induced by wind and are critical for vertical exchanges in stratified water bodies. Turbulence, generated by internal waves, promotes fluxes of solutes and particulates through the metalimnion, the stratified layer separating the warmer, weakly stratified upper mixed layer and the cooler, deeper waters or hypolimnion. Internal wave-mediated fluxes are particularly important for supporting the productivity of lakes during the periods of strongest stratification. The extent of thermocline tilting and nonlinear steepening and wave breaking can be predicted from two related dimensionless indices, the Wedderburn number (W) and its integral form, the Lake (L_N) number (Figure 1). $W = g/\rho (\Delta\rho h^2/u_{*w}^2 L)$ where g is gravity, ρ is density, $\Delta\rho$ is the density difference across the metalimnion, h is mixed layer depth, L is length of the lake, and u_{*w} is the friction velocity in the water and

Stratification and Mixing in Tropical African Lakes,

Figure 1 Extent of tilting of the thermocline for different ranges of the Wedderburn (W) and related Lake numbers (L_N) and predicted changes in magnitude of the coefficient of eddy diffusivity, K_z , used to compute fluxes, $F = K_z \partial C / \partial z$ where C is concentration and z is depth. As W approaches 1, thermocline tilting increases and increasingly two-dimensional processes predominate and induce fluxes (Adapted from MacIntyre (2008)).

is derived from wind stress (Imberger and Patterson, 1989). Typically, u_{*w} is $\sim 0.001U$ where U is wind speed.

Shallow lakes: diel stratification and mixing

Diel stratification and mixing is one of the predominant attributes of shallow tropical African lakes. This pattern was first noted in Nyanza Gulf, Lake Victoria (Worthington, 1930). Lake temperatures are nearly isothermal in the morning, increase rapidly in the upper water column with morning heating, reach a maximum by early afternoon, and then decrease beginning late afternoon becoming isothermal at night with temperatures often similar to those at dawn on the previous day. Diel stratification has been subsequently noted in other African lakes, for example, Jebel Aulia Reservoir, Sudan (Talling, 1957); Lake George, Uganda (Ganf and Viner, 1973); Lake Nakuru, Kenya (Melack and Kilham, 1974); and Lake Kilotes, Ethiopia (Talling et al., 1973). These shallow lakes often have high attenuation coefficients (Secchi depths can be 25 cm) either due to high concentrations of phytoplankton or suspended sediments. Consequently, heat is rapidly trapped in near-surface waters, and due to the relatively large changes in density with small temperature changes in warm water, stratification is pronounced (Figure 2). In lakes with smaller attenuation coefficients, the diel stratification will not be as pronounced (Figure 3). Stratification dynamics can change from day to day if conditions are cloudy, as during rainy seasons, or if afternoons are windy. If winds increase when these lakes are strongly heating, surface currents are intensified and may cause internal waves to form with sufficient shear to cause vertical mixing. As solar radiation decreases,

Stratification and Mixing in Tropical African Lakes,

Figure 2 Time series of temperatures in Lake Nakuru (42 km², maximum depth 3.3 m), Kenya, on November 30, 1976 illustrating morning heating and loss of heat and mixed layer deepening in response to cloud cover reducing solar insolation and gusty afternoon winds between 5 and 7 ms⁻¹. The Richardson number was 0.2 between 11 and 38 cm in the first profile suggesting sufficient shear within the diurnal thermocline to contribute to its deepening. Water was often anoxic below the diurnal thermocline and remained so until the mixed layer homogenized. Arrows indicate depths at which temperatures oscillated likely due to high-frequency internal waves. Duplicate open circles indicate range of temperatures at those times (From MacIntyre (1981)).

mixed layer deepening will be facilitated by increased evaporation and the resulting convective mixing. Time series observations in Lake Elementeita, Kenya, obtained over 13 months indicate a high degree of predictability in stratification dynamics in these shallow lakes (Melack, 2009). As a consequence of the stratification and the high productivity of many of the shallow African lakes, dissolved oxygen concentrations increase and decrease over diel cycles similar to temperature. Oxygen concentrations can reach 200% of saturation during the day. Interestingly, nocturnal cooling, which can induce isothermy, may not fully mix the dissolved gases at night.

Careful analysis is required to assess whether inshore-offshore exchanges are mediated by differential heating and cooling or by other processes (Okely et al., 2010). Time series observations in Pilkington Bay, an embayment in Lake Victoria, indicate that while the nearshore waters of inshore embayments often heat up more during the day than waters further offshore, conditions which could lead to buoyant overflows, wind-driven flows are more likely dominant during the day. Cooling at night can be sufficient to induce gravity currents that would enable exchange between inshore waters and larger channels (MacIntyre et al., 2002). During high winds, both the flows from surface currents and internal wave-induced flows may cause offshore waters to flush inshore channels.

Stratification and Mixing in Tropical African Lakes, Figure 3 Vertical profiles of currents with a warm bead thermistor flowmeter and profiles of temperature (•) and oxygen (o) at 0930 h and 1,200 h on October 27, 1976 in a lagoon of Lake Naivasha, Kenya. Macrophytes were abundant and indicative of attenuation coefficients less than those in the main basin of the lake where $k_d = 1 \text{ m}^{-1}$. Temperatures increased 2.5°C in 3 h. Winds were light, below instrument threshold, 0.8 ms⁻¹, and up to 1.7 ms⁻¹, when the first velocity profiles were made and illustrate the high-near-surface speeds due to surface streaming. Winds averaged 1.2 ms⁻¹ during the second set of profiles. The upper most current measurements were 0.5–1 cm below the air-water interface in the first profile and 1.5 cm below the air-water interface in the second set of profiles (From MacIntyre (1984)).

Use of introduced or biological tracers can be used to infer dominant processes. Fish (1957), for instance, noted a large increase in the abundance of diatoms, originally only found inshore, in offshore waters after a strong wind event. Thus, while temperature differences between inshore and offshore waters may appear conducive for convective exchanges, the full suite of processes must be explored before definitive answers are obtained.

Moderately deep lakes: emergence of seasonality

Temperature differences are only 1–2°C between the surface and bottom waters of the moderately deep tropical lakes. Fish's (1957) time series measurements of temperature in 80-m-deep Lake Victoria indicated that seasonal stratification could develop despite such small temperature differences. His time series data (Figure 4), as well as that of Talling (1966), established that Lake Victoria is holomictic during the southeast monsoon, becomes weakly stratified over its entirety in the calmer, sunnier, and more humid period which follows, and that seasonal stratification develops beginning at the end of the short rains or start of the northeast monsoon in December. The stratification develops as winds in the day mix incoming heat downward forming a seasonal thermocline below 50 m. Thus, development of seasonal stratification takes about 3 months. Diurnal thermoclines remain a prevalent feature, with the depth of nocturnal mixing depending on the extent of nighttime cooling but to depths as great as

50 m during the long rains from February until April or May. Seasonal stratification persists, in general, until late May when cool, dry air masses and higher winds arrive with the onset of the southeast monsoon. The occasional holomixis to the north (e.g., during January in Figure 4), noted since the earliest time series measurements were made, was attributed to wind-induced downwelling of the thermocline. A cross-basin transect in May 1995 during high winds provided the first demonstration of the downwelling of the thermocline to the north and its upwelling to the south. Importantly, observations in other lakes have shown that on cessation of the wind, rocking of the thermocline can induce considerable mixing. Stratification to the north in Lake Victoria was considerably reduced after the event. The loss of seasonal stratification in Lake Victoria may be initiated by increased winds which cause the thermocline to upwell with concomitant mixing but ultimately results from the deep mixing due to heat loss. By June, heat losses, particularly to the south and west, increase threefold relative to other seasons, and, while diurnal thermoclines form in the upper 5 m, mixing at night can reach the bottom. Thus, while diurnal thermoclines form nearly every day in Lake Victoria, the depth of nocturnal mixing varies seasonally, with mixing of order 5–10 m in September, to depths up to 50 m from January through May, and to at least 60 m during the southeast monsoon. The mixing dynamics in Lake Victoria are intermediate to those in shallow lakes, where mixing goes to

Stratification and Mixing in Tropical African Lakes, Figure 4 Time depth diagram of isotherms (lines of constant temperature) for Lake Victoria (68,800 km², maximum depth 80 m), East Africa, 1952–1953, illustrating the well mixed conditions during the southeast monsoon (June, July), the development of weak stratification beginning in August with near-surface stratification due to heating, and stratification induced at depth likely due to flow of a gravity current. Temperature stratification at the beginning of December 1952 was 1.2°C. The buoyancy frequency, $N = g/\rho \, dp/dz$ where g is gravity, ρ is density, and z is depth, was 3.5 cycles per hour. While considered weak stratification by oceanic standards, such stratification is sufficient to support internal waves. For instance, at a deep ocean site near Hawaii where $N = 4$ cph, internal wave motions were 300 m crest to trough. The rising isotherms in October and December 1952 were accompanied by upwelling of water with low oxygen concentrations and are indicative of internal wave activity in the lake. The seasonal thermocline begins to develop in November–December and persists until May. Brief intervals of holomixis in January are likely due to downwelling of the seasonal thermocline during windstorms as indicated in Fig. 1 for Wedderburn numbers near 1 and provide further evidence for internal wave activity (Figure redrawn from Fish (1957)).

the bottom each night, and to those in the deeper African Great Lakes, where mixing during the dry season can reach to depths of 100–150 m.

Lake Albert in the Western Rift Valley is about 58-m deep and exposed to high winds during much of the year. Temperature differences are at most just over 1°C. With these conditions, seasonal stratification is even less likely than in Lake Victoria. Via a series of transects from inshore to offshore waters, Talling (1963) showed that differential cooling, and the gravity currents which result, was a likely cause of stratification deep in the water column during the short and long rains in this Great Lake. Differential cooling is facilitated in Lake Albert ($SA = 5,600 \text{ km}^2$, $z_{\text{mean}} = 25 \text{ m}$) by a shelf region to the southwest which is nearly 20-km long and less than 10-m deep. Thus, nocturnal cooling would typically extend to the bottom of the shelf and cause water temperatures to be cooler there than offshore. Silica and oxygen were strongly stratified below 35 m during the short rains – observations which indicate that even if temperature stratification is weak, pronounced gradients in solutes can develop. Talling hypothesized that horizontal convective processes would cause stratification in other tropical lakes, and there is evidence for it in Lakes Victoria and Malawi.

Deep lakes and the development of meromixis

A defining characteristic of the deep African Great Lakes, Tanganyika, Malawi, and Kivu, is that they are meromictic and, at depths below 100 or 200 m, deoxygenated. That is, they do not fully circulate each year. Anoxia results from the decomposition of organic matter which has settled out of the mixed layer and from the lack of complete mixing which would reoxygenate the lower water column. The upper water column in these lakes undergoes diel stratification and mixing, a seasonal cycle of stratification and mixing dependent on solar insolation and on the movement of the Intertropical Convergence Zone, and associated changes in wind and air masses. Mixed layer deepening is greatest during the southeast monsoon with greater deepening to the south end of the lakes. For instance, mixed layer depths are up to 120 m at the south end of Lake Tanganyika (see Huttula and Sarvala, Figure 3, this volume). The lakes are meromictic because neither the heat losses nor the wind mixing are sufficient to cause mixing to the bottom.

Basin scale tilting of the thermocline during the southeast monsoon is another defining characteristic of these lakes. The upwelling of water from 100 m to the south was noted by Coulter (1963) for Lake Tanganyika, who also pointed out the importance of the upwelling for nutrient supply, primary productivity, and for sustaining the fisheries of the lakes. These detailed observations also indicated internal waves were present during other seasons. Later analysis, based in part on values of Wedderburn numbers less than 1 (Coulter and Spigel, 1991), indicated these would be nonlinear and thus capable of north-to-south transports. Heating rates are greater and heat losses are less to the north than the south of

Lake Tanganyika. Verburg et al. (2011) showed that a convective circulation forms in which warm water from the north is transported to the south in the upper mixed layer and cool water from the south flows north in the thermocline. This flow occurs early in the southeast monsoon (dry season) and persists for nearly 2 months after it ends and is responsible for a substantial redistribution of heat.

Crater lakes and chemically stratified lakes – Volcanic regions occur in mountainous areas in the Cameroon and in the East and West Rift Valleys. Due to phreatic explosions, that is, explosions resulting from magma superheating the groundwater, maar lakes form, with classic examples being Lakes Monoun and Nyos in the Cameroon, Lake Sonachi in Kenya, the crater lakes in Western Uganda, and the Bishoftu Crater lakes in Ethiopia. Many of these have unusual chemical composition. Diurnal heating and cooling occur in these lakes, but crater walls may limit the exposure of these lakes to wind forcing and the depth of mixing may be reduced relative to unsheltered lakes of similar depths (Figure 5). The study of seasonally stratified Lake Pawlo, one of the Bishoftu Crater lakes, was among the first to demonstrate that destratification and even holomixis occur in response to nocturnal cooling despite high solar radiation in the day (Wood et al., 1976). Shallow, closed basin, crater lakes may be meromictic due to freshening of surface waters during rain events and seepage of water with higher salt concentrations in the littoral and their subsequent flow as gravity currents to deeper depths in response to rain (MacIntyre and Melack, 1982). An example is Lake Sonachi, Kenya, whose depth varies from 5 to 8 m. Complete mixture may be possible after persistent droughts reduce the density differences between the upper and lower water column, but meromixis will be maintained if rainfall events are sufficiently frequent.

Lakes Monoun and Nyos, two maar lakes in the Cameroon, and Lake Kivu all share the distinction of having increased concentrations of carbon dioxide in their lower water columns, and due to the relatively recent explosions of Lakes Monoun and Nyos, have been called “killer lakes.” Lake Kivu additionally has elevated methane concentrations. The chemical stratification as well as the great depths of the lakes (Monoun 100 m; Nyos 210 m; Kivu 500 m) ensure that the lakes do not turnover seasonally and are thus meromictic. Due to the concomitant increases in temperature and conductivity, double diffusive convection has been observed in Lakes Nyos and Kivu (Schmid et al., 2004, 2010). If the concentrations of dissolved gases exceed a threshold set by hydrostatic pressure, they will come out of solution, and an explosive bubble plume will form. Lake Monoun last exploded in 1984 and Lake Nyos in 1986, and in the case of Lake Nyos, the gravity currents induced by the massive increase in carbon dioxide flowed into the valleys where people resided causing 1,800 deaths. To avoid future tragedies, pumping systems which vent CO_2 were installed in the two Cameroonian lakes in 2004 (Kling et al., 2005). Plans are being developed to similarly vent the gases in Lake Kivu, with a pilot plant

Stratification and Mixing in Tropical African Lakes, Figure 5 Temperature profiles illustrating diurnal heating and nocturnal cooling in 18 ha Lake Sonachi, Kenya, on 27–28 October 1973. *Left:* (—) 0700 Oct 27, (---) 1050 Oct 27, (···) 1320 Oct 27; *Right:* (—) 1645 Oct 27 (---) 1930 Oct 27, and (···) 0705 Oct 28. The lake is chemically stratified with crater walls 50–115 m above the lake. Two aspects of the stratification are unusual in this figure and likely result from the slight gradients in conductivity within the lake. Heating by 1,320 h 27 Oct occurs below 3 m, but the attenuation of photosynthetically available radiation was 3 m^{-1} which would restrict surface heating to depths above 2 m. Temperature profiles in other months indicated heating and cooling in the upper 2 m as would be expected and near isothermy near dawn. Wind speeds tended to be light in the crater, so vertical mixing was unlikely to have caused the increased heating below 2 m at 1,320 h. Instead, differential heating combined with spatial differences in conductivity likely induced gravity currents which transported heat below 3-m depth. Increased oxygen concentrations below 2 m on other sampling dates also suggest inshore-offshore exchange by gravity currents. The temperature inversions in early evening and in the morning are also unusual and likely persisted due to the weak chemical stratification (From MacIntyre (1981)).

in operation. The 1.2 million people living around Lake Kivu are currently at risk, so ventilation is urgent with the added benefit that the methane will be used to generate electricity and will promote development.

Changes in thermal structure due to changes in climate and land use – Temperatures throughout the water column have increased due to global warming in Lakes Tanganyika and Malawi (Verburg et al., 2003; O'Reilly et al., 2003; Vollmer et al., 2005) with the greatest increase in the upper water column. This increase in stratification has led to a reduced flux of nutrients into the upper water column of Lake Tanganyika and a reduction in the abundance of diatoms. Consequences of these changes for the fisheries in these lakes are not yet known. Hecky (1993) reported increased water temperatures and stability in Lake Victoria and an increase in the volume of anoxic water since Talling's measurements in 1966. The increased anoxia is a result of land use changes in the basin. Time series temperature data from 1994 to 1996 indicate interannual variability in the extent of warming. Whether increased stability, which will contribute to persistent anoxia, is a trend or whether it will vary likely depends on the many factors influencing East African climate. For example, rainfall in the Lake Victoria region

varies with phase of the El Nino-Southern Oscillation and of the Indian Ocean Dipole (Nicholson and Yin, 2002; Williams and Funk, 2010). Wind records based on reanalysis of satellite data and land-based data from 1948 through 2010 indicate conditions were windier in the early 1950s and 1960s than in the mid-1990s. Winds were again high near 2000. Thus, temperatures and mixing dynamics in moderately deep tropical lakes may show considerable year-to-year variability. Winds over the tropical African lakes are sensitive to changes in sea surface temperature and upwelling in the Atlantic, Pacific, and Indian Oceans. While increased air temperatures may predominate due to global warming, the other factors which affect mixing dynamics will remain variable.

STRATIFICATION IN LAKES

Timo Huttula

 Jyväskylä, Finland

Synonyms

Layered structure of lakes; Non-mixed lakes

Definition

Stratification is defined as the development of relatively stable light and warm layers above colder deeper layers within a body of water. Thermal stratification is related

to water density and is effected by incoming heat, water depth, and the degree of water-column mixing.

Introduction

Lakes receive thermal energy mainly through the lake surface. Part of the shortwave energy from the sun penetrates through the surface and is absorbed in the near-surface layers. In a typical lake this happens within the uppermost 10 m, but in very clear water lakes this penetration can reach down to tens of meters. Long-wave energy from clouds and the atmosphere is absorbed within the first centimeters in the lake water body. Thermal energy is also exchanged between the lake bottom and the lake water body, but normally it has only a secondary role in lake thermodynamics.

Accumulation of thermal energy in the near-surface layers will move the center of gravity of the lake upward and thus the potential energy of the lake water body is increased. Moving it downward and mixing the lake water vertically requires mechanical energy, which is supplied by the wind.

Water temperature determines the density in freshwater lakes. The density maximum at 3.98°C water temperature has a fundamental effect on the development and destruction of the lake stratification.

Stratification has many ecological consequences. During the stratified period, the metalimnion effectively prevents water-column mixing, isolating the hypolimnion from gas exchanges with the atmosphere. In

addition, the hypolimnion is often too poorly lit for photosynthetic production of oxygen by green plants. Without an influx of oxygen, the hypolimnion can become depleted of oxygen during the summer stratified period due to oxygen use by bacterial decomposition of organic matter.

Annual cycle of lake water temperature

The annual cycle of lake water temperatures in temperate lakes is typically as follows. In spring during ice melting, or even during the snow-free period before the ice melting, an overturn, a complete vertical mixing, of the lake water body happens (Figure 1). Another overturn happens in autumn, when the surface waters have been cooled so that they are lighter than the deep waters. The length of the autumn overturn is very much dependent on the autumn weather and is anyway longer than the spring overturn. The overturn is important to the vertical exchange and renewal of deep abyssal waters, their oxygen enrichment, and the life in them.

In summer most of the lakes in the temperate climatic zone are stratified. The almost homothermal surface layer extending down to 5–20 m is called the epilimnion (Figure 2). Under it is the metalimnion, where the water temperature decreases rapidly. The plane with maximum decrease is called the thermocline. The metalimnion is usually some meters thick. Under this is a cool layer with an almost homothermal structure which is called the hypolimnion.

Stratification in Lakes, Figure 1 The annual mean course of water temperature during the period 1981–2000 as isotherms in Lake Kallavesi, Finland, at the Säyneensalo (From Korhonen, 2002).

Stratification in Lakes, Figure 2 Typical thermal stratification of a lake into epilimnetic, metalimnetic, and hypolimnetic water strata. Dashed lines indicate planes for determining the approximate boundaries of the metalimnion (From Wetzel, 2001).

Stratification in Lakes, Figure 3 Two water temperature profiles in Lake Kallavesi, Finland. One from late winter, when the lake was still ice covered, and one from the period of strong stratification.

In winter waters just underneath the ice have a temperature near 0°C. The deep abyssal waters have a temperature somewhat below the temperature of maximum density (Figure 3).

The temperature in small humic lakes can rise as the oxygenation of organic compounds produces small amounts of heat. Also in some lakes heat released from sediments and convective accumulation of heated waters to the abyssal areas is seen as a temperature increase of deep waters.

Besides the seasonal temperature and stratification variation, diurnal variations are also found in the lake water

body. This happens especially during calm cloudless summer days and nights. The solar radiation heats up the surface waters increasing daytime stratification with some extra layers in the epilimnion. Nocturnal cooling of air leads to strong sensible heat loss from the lake surface, which is also emitting heat by long-wave radiation. The cooled waters sink down and cause vertical mixing and this leads to the homothermy of the epilimnion.

Lake classification based on thermal stratification

The stratification variation as presented above is typical in the temperate climatic zone, where lakes are most abundant. A lake presenting this type of stratification is called dimictic. A lake classification system based on stratification and circulation patterns has been introduced by Hutchinson and Löffler (1956) and Hutchinson (1957). Monomictic lakes have one turnover period in a year. Cold monomictic lakes are situated in the arctic zone with water temperatures never rising above 4°C. Warm monomictic lakes are situated in the subtropics with water temperatures never cooling down to 4°C. Oligomictic lakes face turnover very seldom. It can happen, for example, in stormy periods. Polymictic lakes face the turnover several times in a year. Cold polymictic lakes circulate continually at temperatures near or slightly above 4°C. A warm polymictic lake is usually a tropical lake that exhibits frequent periods of circulation at temperatures above 4°C. A cold amictic lake never has a turnover as it has a perennial ice cover. In meromictic lakes vertical mixing happens in the epilimnion and metalimnion but hypolimnetic waters are amictic. Typically deep tropical lakes, like Lake Tanganyika, are meromictic. The relationships of thermal lake types with altitude and latitude are presented in Figure 4.

Lake water stability

Stability (S) per unit area of a lake is the quantity of work or mechanical energy in Jm^{-2} required to mix the entire volume of water to a uniform temperature without heat exchange with the environment (Birge, 1916; Schmidt, 1928). During summer stratification, stability expresses the amount of work needed to prevent the lake from developing a thermal stratification. Thus stability quantifies the resistance of the prevailing stratification to disruption power by the wind. In a particular lake it varies during the course of the summer and from year to year (Figure 5).

Effects of global warming on lake stratification

The effect of global warming on lakes in the temperate zone has been studied actively during the recent decades (Kuusisto, 1989; Huttula et al., 1992; Elo et al., 1998). The main method has been mathematical modeling. Future scenarios in both shortwave and long-wave heat balance components of the lake surface are available in the models. The lack of wind scenarios weakens the lake modeling results and most of the lake simulations have been made with present winds. It seems, however, that the increase of air temperature leads to earlier melting of

Stratification in Lakes, Figure 4 Schematic arrangement of thermal lake types with latitude and altitude. The areas with no label (horizontal and crossed bars) present transitional regions. Likewise the broken vertical bars between oligomictic and polymictic lakes present regions of mixed types, mainly warm monomictic lakes (From Wetzel, 2001).

Stratification in Lakes, Figure 5 Stability of the representative area in Kallavesi during the period 1981–2000 (From Korhonen, 2002).

snow from the lake ice surface and earlier ice cover melting than in present climate. This will happen 1–2 months earlier than at present (Huttula et al., 1992; Elo et al., 1998). The formation of ice cover will happen a few weeks later than at present and in large lakes ice-free winters will

become more frequent than at present. The surface temperature increase in summer will follow the temperature increase of the air. The fate of thermal stratification depends on the changes of the wind by large. It seems that in deep large lakes the epilimnion will deepen from present and

may even change some dimictic lakes to polymictic lakes. Also some sheltered lakes may face turnover also in spring instead of in autumn. They presently start to stratify already with the ice cover on (Saura et al., 1996).

Summary and conclusions

The special density distribution due to water temperature leads to thermal stratification in lakes, where a relatively stable, warm layer is found near the surface and colder layers in deep waters. In between there is a layer with a rapid water temperature decrease. It is called the metalimnion. In wintertime, inverse stratification is found. There the coldest and lightest waters are found near the surface and the warmest waters approaching the temperature of maximum density are in the deep layers. Many versions of this basic system are found depending on the lake's latitude, altitude, and wind forcing on the lake. The stratification of lakes has many ecological consequences. Global warming will change the lake stratification, basically by increasing the surface layer temperature and extending the open water period in lakes in the temperate zone.

 Submerged (submersed) plants

Definition

Submerged plants. Plants in which the shoots and leaves are totally restricted to the water column. Inorganic carbon is either taken from the water or the sediment. Flowers may stretch above the water surface. The plants can be rooted or free-floating and belong to the vascular plants, mosses (bryophytes), stoneworts (Characeae) and macroalgae.

Introduction

A distinct zonation of plants can be observed across the lake shoreline: Below different types of terrestrial vegetation only occasionally affected by flooding, reedbelts with different species of emergent plants dominate on water-saturated and submersed soils down to a depth of about 1.5 m. Outside the reedbelts, floating-leaved plants can occur at water depths from around 0.5–3 m, but lack in wind-exposed areas. While these two plant life-forms are spreading across the water-atmosphere interface and assimilate atmospheric carbon dioxide during photosynthesis, submerged plants, which occur at all depths, are mainly restricted to the submersed environment (Wetzel, 2001).

Adaptations to the submersed environment among submerged plants

Compared to the terrestrial situation, the submersed environment offers specific conditions, which submerged plants respond to by both morphological and physiological adaptations. Drought adaptations such as thick cuticles (see exception below: isoetids) and leaves covered by hairs are lacking among submerged plants, and in most groups, root biomass is rather low. Due to high buoyancy within the water column, supporting tissues are reduced, lignin is generally lacking in submerged plants, and cellulose content is low. Nutrients such as nitrogen and phosphorus can be taken up both from sediment and water column. Finely dissected leaves are common among submerged plants and facilitate the uptake of these nutrients as well as inorganic carbon (see below) (Wetzel, 2001).

Solar insolation reaching the water surface is partly reflected, and only part of this light is entering the water column. On its way down, this light decreases due to

absorption by dissolved substances (water color) and scattering by particulate material (both organic and inorganic). The attenuation (vertical decrease of light through the water column) varies substantially among lake types, but generally, the submersed environment can be characterized as a low-light habitat (Scheffer, 1998; Wetzel, 2001). In submerged plants, chloroplasts are often situated in the epidermis of the rather simply structured leaves. Physiologically, low light compensation point and low light saturation point as well as low maximum photosynthesis rate characterize submerged plants as typical shade-adapted plants (Pott and Remy, 2000; Wetzel, 2001).

One of the main factors limiting primary producers in the submersed environment is carbon availability. Submerged plants have developed different mechanisms for carbon acquisition (see below). Like other aquatic plants, submerged vegetation has to cope with anaerobic conditions within the sediments. Gas transport from the leaves down to the roots and rhizomes facilitated by extensive aerenchymas is one mechanism of adaptation to anaerobic soils. Another main mechanism is physiological adaptations to different toxic substances typical in anaerobic soils (Wetzel, 2001).

Several submerged macrophytes like *Zannichellia* spp., *Vallisneria* spp., and *Ruppia* spp. are hydrophilous, i.e., the pollen is spread by the water. More common is wind pollination (anemophily) which occurs in species that develop flowers above the water surface (*Myriophyllum* spp., *Potamogeton* spp.). A third mechanism of pollen dispersal is insect pollination (entomophily), which occurs in *Utricularia* spp. and other submerged macrophytes.

Water is the most common transport vector for seed dispersal in submerged macrophytes. To colonize remote lakes and reservoirs, transport by animals is common, especially transport of seeds and oospores within the intestine system of waterfowl.

Apart from this sexual reproduction, vegetative propagules are commonly formed in submerged macrophytes, many of which serving as specified hibernacles like condensed shoots (turions) in *Utricularia* and *Myriophyllum* or belowground tubers in *Stuckenia pectinata* (former *Potamogeton pectinatus*) (Pott and Remy, 2000).

Different growth forms of submerged macrophytes

Among submerged plants, angiosperms are represented by different growth forms (Figure 1). Isoetids are typical for softwater lakes with low or moderate nutrient concentrations and clear water. This bottom-dwelling life-form is represented by a number of species such as *Isoetes* spp. (Pteridophyta: Isoetaceae), *Littorella uniflora* (Plantaginaceae), *Lobelia dortmanna* (Lobeliaceae), and *Subularia aquatica* (Brassicaceae). In spite of their belonging to taxonomic groups rather distant from each other, all species are morphologically similar in a way that it is sometimes hard to distinguish them from each other. Common characters are a rosette growth form and short leaves, high ratio of root/shoot biomass, extended

aerenchymas, and a thick cuticle (Pott and Remy, 2000; Wetzel, 2001).

Apart from isoetids (see above), submerged angiosperms are taller and often characterized by more or less finely dissected leaves. Among this elodeid growth form, many species are erect (e.g., *Elodea*) forming long shoots in the water column. Other species have a canopy-like growth form (e.g., *Stuckenia pectinatus*) in which the shoots divide first in their upper parts. This growth form mainly occurs in nutrient-rich, turbid water. A few elodeid angiosperm species are non-rooted (e.g., *Ceratophyllum*).

Stoneworts occur in different lake types. While softwater lakes are mainly inhabited by different *Nitella* species and only few species belonging to the genus *Chara*, *Nitellopsis obtusa* and most species of the genus *Chara* mainly occur in nutrient-poor hardwater lakes where they can form dense mats and dominate the submerged vegetation (Wetzel, 2001; Figure 2). Characeae are macroalgae belonging to the division Streptophyta. They are bottom-dwelling plants forming branched thalli attached to the sediments by thin, thread-like rhizoids.

Submerged plants and eutrophication

With increasing nutrient loading, a dominance shift occurs among primary producers in shallow lakes. Free-floating microalgae (phytoplankton) as well as attached microalgae (periphyton) which only can take up nutrients from the water column are favored by this nutrient increase. Submerged plants, which can take up nutrients also from the sediments, suffer from increasing shading by both periphyton and phytoplankton and decrease drastically at a certain critical nutrient loading (Phillips et al., 1978). Internal feedback mechanisms explain this sudden shift (see chapter *Alternative Stable States in Shallow Lakes*).

Among submerged plants, bottom-dwelling growth forms (isoetids and stoneworts) depend on high light availability at the sediment surface (van den Berg et al., 1998). This life-form is therefore most sensible to higher turbidity during increasing nutrient loading and often disappears from eutrophied lakes (Wetzel, 2001) or is restricted to very shallow water (Blindow, 1992). Both isoetids and charophytes are therefore used as bioindicators for high water quality (Schneider and Melzer, 2003; Søndergaard et al., 2010). In erect and canopy-producing angiosperms, rapid shoot elongation is common at poor light availability (Barko and Smart, 1981). Canopy-producing plants concentrate the major part of their biomass close to the water surface where light availability is at its maximum (Titus and Adams, 1979). Large hibernacles enable a high initial growth rate during spring even under turbid conditions (Titus and Adams, 1979; Moen and Cohen, 1989). In shallow, turbid lakes, canopy-producing plants like *Stuckenia pectinatus* can grow down to about 1 m depth independently of turbidity (Blindow, 1992; Scheffer et al., 1992).

Submerged plants and carbon assimilation

In the submersed environment, dissolved carbon dioxide (carbonic acid) is in continuous exchange with atmospheric carbon dioxide. When carbon dioxide is produced or consumed within the water column by processes like photosynthesis or respiration, the equilibrium between air and water is restored by diffusion. This is a rather slow process, however, causing deficiency in inorganic carbon when aquatic photosynthesis is rapid.

Dissolved carbon dioxide (CO_2) forms a chemical equilibrium with bicarbonate (HCO_3^-) which in turn is in equilibrium with carbonate (CO_3^{2-}). These equilibria are pH-dependent: Only in acid and subneutral water, carbon dioxide is the main form of inorganic carbon, while bicarbonate dominates in neutral to slightly alkaline water and carbonate in highly alkaline water (Wetzel,

2001). In hardwater lakes, calcium carbonate (CaCO_3) is precipitated and forms an additional pool of inorganic carbon.

For submerged plants, inorganic carbon is a critical limiting factor. Carbon dioxide is the preferred form of inorganic carbon and easily taken up by all species. In softwater lakes, the inorganic carbon is therefore easily available, but the total pool is rather limited. In hardwater lakes, which are characterized by slightly alkaline conditions, the dissolved pool is replenished from the insoluble CaCO_3 pool upon consumption. In these lakes, the total amount of inorganic carbon is far higher, but dominated by bicarbonate which is not easily available for assimilation.

While some submerged plants are restricted to uptake of dissolved carbon dioxide (e.g., water mosses), most

Submerged Vegetation in Shallow Lakes, Figure 2 Dense mats of the stonewort *Chara rudis* in a calcium-rich alpine lake in southern Germany (Photo: Klaus van de Weyer).

species have evolved specific strategies for carbon assimilation (Madsen and Sand-Jensen, 1991). Carbon storage at night (CAM metabolism) is common among isoetids (Keeley, 1998). Plants belonging to this group are also able to take up carbon dioxide from the sediments. The specific morphology of this life-form (see above) facilitates the upward transport of carbon dioxide to the chloroplasts. Other species (e.g., *Myriophyllum* spp., *Potamogeton* spp.) develop aerial leaves which allow access to the atmospheric pool of carbon dioxide. By far the most important adaptation of carbon uptake and widespread among submerged angiosperms and stoneworts is bicarbonate assimilation. Different mechanisms have been proposed for bicarbonate uptake, each involving active, ATPase-mediated proton fluxes across the cell boundaries. (Madsen and Sand-Jensen, 1991; Ray et al., 2003).

Submerged vegetation in different lake types

The different adaptations to light and carbon limitation among submerged plants explain the restriction of different life-forms to specific lake types.

CAM metabolism and uptake of carbon dioxide from the lake sediments give isoetids a competitive advantage under the conditions of low carbon availability in softwater lakes. Significant use of sediment CO_2 has not been found in erect and canopy-producing angiosperms possibly due to long transport paths and low root biomass (Madsen and Sand-Jensen, 1991). Eutrophication of softwater lakes not only causes an increase in plant nutrient concentrations like nitrogen and phosphorus but is also accompanied by an increase of the lake's buffer capacity

and carbon pool. Erect and canopy-forming angiosperms gain advantage under increased availability of inorganic carbon in the water column and outcompete the bottom-dwelling isoetids (Spierenburg et al., 2009).

Oligotrophic hardwater lakes are often dominated by stoneworts. Bicarbonate is strongly withdrawn above dense beds of stoneworts probably due to both uptake and precipitation of CaCO_3 (van den Berg et al., 1998). As *Chara* species use bicarbonate efficiently and have high growth rates even at low levels of inorganic carbon (van den Berg et al., 2002), they may have a competitive advantage under these conditions. Also in this lake type, however, erect and canopy-producing angiosperms dominate under high nutrient concentrations as they can shade and outcompete the bottom-dwelling stoneworts (Moen and Cohen, 1989).

Interactions between submerged plants and microalgae

Free-floating and attached microalgae (epiphyton) are favored by increasing nutrient concentrations in the water column and affect submerged macrophytes negatively mainly by shading (see above). Interactions between epiphyton and its plant substrates are common and complex and include, but are not restricted to competition for nutrients and carbon (Wetzel, 2001). Different toxic substances have been isolated from a number of submerged plants. Apart from their possible function as protection against herbivory, these substances often inhibit microalgae. Such allelopathic interactions are probably common within the submerged vegetation (Gross, 2003).

Submerged plants in the trophic web

In shallow lakes, submerged vegetation can form substantial biomass. In such lakes, submerged plants act as a key factor having substantial impact on all levels of the trophic web. Apart from offering food to waterfowl and fish, the vegetation offers food and protection for zooplankton, macroinvertebrates, and small fish; accumulates nutrients; reduces sediment resuspension; and determines the structure of the microbial community (see single chapters in Jeppesen et al., 1998). Due to its positive effect on water clarity, (re)establishment of submerged vegetation is one of the major goals during biomanipulation (see chapters [Lake Restoration](#) and [Alternative Stable States in Shallow Lakes](#)).

Summary

In submerged plants, shoots and leaves are situated within the water columns. The plants are adapted to life below the water surface by a number of morphological (e.g., reduced supporting tissues, finely dissected leaves) and physiological adaptations (shade adaptation in photosynthesis). One of the most important factors limiting photosynthesis is assimilation of inorganic carbon which is taken up either as free carbon dioxide or bicarbonate from the water phase. In isoetids, a life-form with rosette leaves typical for softwater lakes, sediments serve as source for carbon dioxide. Ground-dwelling plants like isoetids and stone-worts are sensitive against eutrophication because of light limitation, while erect elodeids and especially canopy-forming species are more tolerant.

SURFACE SEICHES

Ulrich Lemmin

ENAC, Ecole Polytechnique Fédérale Lausanne (EPFL),
 Lausanne, Switzerland

Definition

A seiche is a standing surface wave in an enclosed or partially enclosed body of water.

In a lake, a surface seiche is most often produced when wind that has created a storm surge at the end of the lake suddenly ceases ([Figure 1](#)). Due to the restoring force of gravity, the lake surface first goes back to the still water level, and then, due to the inertia of the system, it overshoots and continues to oscillate around the nodal point in the center of the lake ([Figure 1](#)). The nodal point experiences no vertical motion. Maximum amplitudes occur at antinodes at the basin ends. Detailed observations of this

Surface Seiches, Figure 1 Definition sketch for a uninodal surface seiche in a rectangular basin. *Black dot*: nodal point, *A*: antinodes, *dashed line*: still water reference surface level, and *arrows*: mean orientation of water mass movement.

surface oscillation were made in Lake Geneva by Forel (1895) who used the term “seiche” to describe this motion. Seiche motion slowly decays under the influence of friction, and a decay rate of about 3% for each seiche period has been estimated for Lake Geneva.

This movement can be approximated by a standing wave with a wavelength L that is twice the basin length L_b (Figure 1). If $h/L_b < 0.2$, which is the case in most lakes, shallow water wave conditions apply. Starting from the depth-integrated mass transport equations, an equation for the period of surface seiches can be obtained from the resulting equation for the surface elevation η .

$$\frac{\partial^2 \eta}{\partial t^2} - c^2 \frac{\partial^2 \eta}{\partial y^2} = 0$$

This is a simple 1D wave equation. One can find a wave solution for this equation by taking the storm surge solution and adding a series of stationary waves that satisfy

the initial conditions. The resulting seiche period has the following form:

$$P = \frac{2L_b}{n\sqrt{gh}}$$

This equation is known as the Merian equation. The period of the oscillation is determined by the geometry of the basin. For lakes of a given length L_b , the mean depth will modify the period inversely. The number of nodes n determines the order of the surface oscillation. The period of the fundamental seiche mode (uninodal) is given by $n = 1$. It was found that this equation also provides good estimates for real basins, as long as they have a fairly regular shape. The periods of seiches in lakes typically fall into the range of minutes (e.g., the period of the fundamental seiche in “Lake Geneva” is about 73 min, Figure 2). For higher harmonics, $n > 1$, deviations in the observed period from the above equation may occur due to the

Surface Seiches, Figure 2 Recording of surface seiches in Lake Geneva (at Morges, Switzerland). Two different seiche oscillations are superimposed in this recording: the seiche along the long axis of the lake with a period of 73 min (marked by eye by full triangles) and a transversal seiche with a period of about 10 min. Note that the transversal seiche slightly changes periods over time due to the irregular shape of the basin (Modified after Forel, 1895).

irregular shape of a lake basin. If the basin is open at one end, such as in a harbor or a bay, the connecting line to the open lake has to be a node. The corresponding period for the lowest order seiche is twice that of the lowest order seiche that would exist, if the basin were closed.

A seiche is a surface wave and, thus, generates shallow-water wave-type movement within the lake which periodically varies in time and space (Figure 1). Over the period of a seiche, the lake system oscillates twice between a maximum of potential energy (no flow, Figure 1) and a maximum of kinetic energy (Figure 1, flat surface). Typical seiche amplitudes may range from a few centimeters in small to medium sized lakes to tens of centimeters in large lakes. The resultant seiche currents are smaller than other types of lake currents. The period and the currents of a seiche in a lake basin of irregular shape can be analyzed by a numerical model proposed by Defant (1918).

SUSPENDED SEDIMENT CONCENTRATION IN STRATIFIED LAKES ESTIMATED BY ACOUSTIC METHODS

Şebnem Elçi

Department of Civil Engineering, Izmir Institute of Technology, Urla/Izmir, Turkey

Introduction

A wide variety of techniques have been used to measure sediment concentration in rivers, such as conventional samplers, optical method instruments, and acoustic instruments. Acoustic Doppler current profilers (ADCP) and velocimeters (ADV), while their primary use is for velocity measurements, also provide information about the quantity and type of particulate matter in the water. Recent research has been on the use of acoustic methods to measure suspended sediment concentration (SSC), since an acoustic instrument can replace conventional turbidity meters and provide information about velocity, temperature of water, and sediment concentration time series simultaneously.

Using acoustic instruments for SSC measurements in water bodies has many advantages. These advantages include simultaneous measurements and description of the whole water column and sediment suspension structure. Furthermore, ADCPs can be used from a moving boat, eliminating the need to anchor the boat. When an acoustic instrument is calibrated for a water system, no additional sensor is needed to measure SSC, which enables the researchers the simultaneous measurements of velocity and concentration required for most sediment transport studies. Also, turbidity-measuring instruments use optical methods which have limitations for biological fouling. In spite of the advantages, the primary barrier to the development of a comprehensive sediment concentration prediction methodology by acoustic methods has been the lack of sufficient coupled observations of turbidity and acoustic Doppler velocity measurements to develop such a relation. One of the limitations of using acoustic instruments for SSC predictions is that they measure the velocity of acoustic targets (e.g., solid particles) rather than the fluid velocity where the sediment and fluid are assumed to travel at the same velocity. This assumption is likely to be valid only when considering fine sediments dominantly in suspension. For coarser particles (e.g., sand), this effect may introduce additional uncertainty. Another limitation is that, as the sediment concentration increases, acoustic waves are absorbed in sediment-laden flow and attenuated where the acoustic instrument cannot operate properly in high sediment concentrations. These limitations should be taken into consideration when predicting SSC using acoustic methods.

An ADCP estimates horizontal and vertical velocities as a function of depth by using the Doppler effect: a change in the observed sound frequency that results from relative motion toward or away from the sound source. An ADCP utilizes the Doppler effect by transmitting sound at a fixed frequency and listening to echoes returning from sound scatterers in the water so that the relative velocity between the instrument and scatterers in the water is measured. Velocity profiles are produced by dividing the echo into depth cells. Data are averaged vertically in each depth cell, the height of which is defined by the operator. For specifics of the instrument capabilities and configuration options, the reader is referred to the user's manuals (SonTek, 1998; RD Instruments, 2001).

The magnitude of acoustic reflection from the water (signal strength) is a function of the instrument used (influenced by frequency, transmit power, receive sensitivity, and range to the measurement volume) and the conditions of the water which is affected primarily by the type, size, and concentration of particulate matter.

Relative changes in suspended sediment can be determined directly from the changes in signal strength data, assuming a constant sediment type and size distribution. Signal strength data can be converted to measured suspended sediment concentration by comparing acoustic data to water samples and other instrumentation.

Recent research has been on the potential of ADCPs to estimate suspended sediment concentration and bed load (Alvarez and Jones, 2002; Creed et al., 2001; Kostaschuk et al., 2004; Rennie and Villard, 2004). However, these studies were limited to rivers and estuaries or the transport of sand and gravel. Measurements of bed load velocity using ADCPs have been compared with bed load samplers in sand and gravel reaches of a river (Kostaschuk et al., 2004). For gravel beds, bed load velocity was found to be correlated with sampler measurements, and the results were influenced by sediment size, although the effect of particle size was not investigated thoroughly. Studies conducted in estuaries (Alvarez and Jones, 2002; Creed et al., 2001) showed that ADCP performed better for the sediments which have the size distribution close to wavelength of the ADCP output frequency. Also, in both studies, signal strength of the ADCP was affected by salinity fluctuations, beside sediment particles in the water column. However, the effect of salinity was not investigated thoroughly. In a recent study conducted by the author (Elçi et al., 2009), different parameters affecting the performance of an ADV for the prediction of SSC are investigated through measurements made in different streams located in the Aegean region of Turkey having different soil types. A prediction model is presented in this paper relating signal to noise ratio (SNR) readings to SSC measurements where both water temperature and sediment characteristic type are incorporated into the model.

The primary barrier to the development of a comprehensive sediment concentration prediction method has been the lack of sufficient coupled observations of turbidity and acoustic Doppler velocity measurements to develop such a relation. Current methods (Kostaschuk et al., 2004; Rennie et al. 2002; Rennie and Villard, 2004) are capable of predicting SSC in rivers or canals, but application does not exist for stratified environments.

This paper discusses comparison of particulate matter quantity as received by the use of SonTek's RiverCat (1500 kHz ADCP system) and DKK-TOA's WQC-24 (multiparameter water quality meter). Its purpose is to improve the methodology used for prediction of sediment concentration by acoustic methods in stratified environments. Measurements of suspended sediment concentrations and flow velocities were conducted simultaneously when the boat was attached to a buoy in the lake. These measurements were repeated every month including the summer period, when the lake was strongly stratified.

Instrumentation

Measurements of SSC by a water quality meter and flow velocities by ADCP were made simultaneously at the lake. The water quality meter used here measures turbidity by using the scattered light measurement method (Figure 1). Turbidity measurements provide a reading of the amount of scattered light. Turbidity is expressed in terms of the optical property causing the light beam passing through the sample of the fluid to be scattered and absorbed

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 1 Illustration of scattered light measurement method and the instrument used for measurements.

rather than transmitted through the sample. In this study, turbidity measurements were made using DKK-TOA's multiparameter water quality meter. The data accuracy for turbidity was $\pm 3\%$. The relationship between the suspended solids in the liquid and the light intensity due to particle scatter is determined by the factory calibration of the instrument (1 NTU of turbidity corresponds to 1 mg/L of SSC). In the laboratory, the relationship between SSC and turbidity was tested, and a linear relationship was found (Elçi et al., 2009). Water quality data were recorded at 1-m intervals in the vertical. Time series measurements of water temperature and water quality data were recorded at 30-min intervals.

A SonTek ADCP (1.5 MHz) system was used in this study (Figure 2). A 1.5-MHz ADCP can operate to a profiling range (depth) of about 25 m which depends on the speed of sound, which is a function of water temperature, salinity, and sediment concentration. Data are averaged vertically in each depth cell defined by the user during the measurements. Averaging the data is important to reduce possible errors due to ADCP signal to noise ratio, frequency, depth cell size, number of pings averaged, and beam geometry.

Method

Signal strength data from current profilers were corrected for the depth at which suspended sediment concentrations were measured. Signal strength decreases with range from the system due to geometric spreading and absorption. The maximum profiling range for the system used was 15–25 m, varying according to the operating conditions of the ADCP. In Tahtali Lake, data were collected and stored internally and averaged every 5 sec with a cell size

of 0.5 m (Figure 3). The blanking distance of the instrument, where undefined data close to the transducer are blanked out, was 0.44 m.

Fifty cells were selected for this application since the lake was shallower than 25 m. The water depths at the sampling stations were determined by the bottom track option where the pulse hits the bottom. These depths were also verified by the depth sensor of water quality meter.

The water quality meter and the ADCP were synchronized, and the temperature, turbidity, and velocity readings were recorded. The suspended sediment concentrations were measured at the vertical profile within 1-min intervals (the shortest interval time that can be selected by the user). The SNR readings taken by the ADCP corresponding to these depths and times were selected, and the comparisons were made.

The profile of SSC was estimated using a multi-step process including:

1. Calculating transmission loss from spreading and absorption as a function of range and absorption coefficient by the modified equation provided by SonTek (1997) (Equation 1) by a factor of C , where C is defined as a measure of stratification in the water column (Equation 2):

$$Decay = (-20 + C) \times \log 10 \left(\frac{D}{\cos \theta} \right) - 2\alpha \left(\frac{D}{\cos \theta} \right) \quad (1)$$

$$C = 20 \times \left(\frac{h_t}{h} - 0.5 \right) \quad (2)$$

where

$Decay$ = Predicted signal strength loss (dB)

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 2 Illustration of the operation of an ADCP and parameters used to determine ADCP down-looking profiling range and the system (RiverCat with fiberglass pontoons) used for measurements (From SonTek, 1997).

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 3 Bathymetric map of Tahtali Lake. The darker area represents the deepest region of the lake corresponding to 27 m. The buoy, where measurements were made, is shown by a circle.

D = Vertical range from the system (m)

θ = Transducer beam mounting angle (standard is 25°)

α = Absorption coefficient (0.6 dB/m for 1,500 kHz ADCP system)

$\frac{h_t}{h}$ = The ratio of depth of the epilimnion to the total depth of the water column

2. Determining relative backscatter from the velocity measurement for the water column and correcting for the transmission loss (decay)
3. Comparing to the turbidity data simultaneously measured with the ADCP and obtaining an equation for regression between measured turbidity and ADCP data

Close to the transducers, acoustic beams deviate from the spherical spreading in which acoustic signal is inversely proportional to distance from the transducers. This distance is given in Equation 3 by SonTek (1997):

$$d = \pi r^2 / \lambda \quad (3)$$

where r is the transducer radius ($r=2.4$ cm), and λ is the acoustic wavelength ($\lambda=1$ mm); d is calculated as 1.8 m. Therefore, it is necessary to consider the fact that ADCPs can not predict above this distance when estimating suspended sediment concentration at the near surface.

Study site

The observations were conducted in a thermally stratified water supply reservoir, Tahtali Reservoir in Turkey (Figure 3). Tahtali Dam was projected as a rockfill dam and completed in 1996 to supply fresh water to Izmir, the third largest metropolitan area with over three million population. The capacity of the dam is 175 million cubic meters, and it generates monthly five million cubic meters water. The dam is currently operated by IZSU (Izmir Water and Sewage Administration). Tahtali Reservoir has a surface area of 20 km², a mean depth of 15 m, with a maximum depth of 27 m. The major inflows are from North via Sasal Stream and Tahtali Stream. Sasal Stream contributes 25%, whereas Tahtali Stream contributes 75% to the total inflow. The discharges of the other four streams are negligible. The withdrawal point is at South-west location of the lake from the deepest area corresponding to 27 m. The water is provided as drinking water for the city of Izmir after being treated (Çaliskan and Elçi, 2009).

Field applications

Examples of field applications are provided in Tahtali Lake where ADCP and the multiparameter water quality meter were deployed at monthly intervals to investigate the effects of stratification. The SNR readings and suspended sediment concentration data were measured

simultaneously when the boat was attached to a buoy in the lake. The location of the buoy is shown in the bathymetry map of Tahtali Lake (Figure 3).

The observed temperature profiles at the buoy are given in Figure 4. Depth of the water column where buoy is located was 18 m. As one can see in the figure, stratification was evident in August where water temperature at the surface reached 28°C, and the thermocline started at a depth of 10 m. In October, however, surface temperatures decreased to 21.5°C, and the thermocline moved to a depth of 14 m, indicating mixing of most of the water column (Elçi, 2008).

The variation of turbidity profiles measured by the water quality meter is presented in Figure 5. Turbidity peaks are found mostly in the thermocline region. Turbidity increases are closely related to the maximum density gradient, which has the low turbulence level. A noticeable increase in turbidity toward the bottom of the lake on 17 October 2006 was probably due to the effect of the relatively cold sediment-laden water flowing into the lake after the rain event (no rain was observed in the study site from June to October 2006). Total of 3.5 mm rain was collected at the weather station during the last 3 days prior to the data collection on 17 October 2006, leading sediment concentration to double below the thermocline.

Figures 6 and 7 illustrate profiles of ADCP backscatter and suspended sediment concentration measured at a buoy on different dates. As can be seen in these figures, SNR data obtained from the RiverCat matched the turbidity data collected by the water quality meter well, especially within the thermocline. However, below the thermocline, turbidity values were underpredicted. This can be explained by the operation principle of the ADCP. The profiling range of the ADCP is a function of the acoustic frequency and the strength of the scattering return from the water. On 31 August 2006, for instance, thermocline had reached 10 m depth, and 12 mg/l was observed at that depth which was the maximum through the water column. From 10 m of depth to the bottom of the lake, the turbidity gradually decreased, indicating the decrease of the amount

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 4 The observed temperature profiles measured by the water quality meter at the buoy.

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 5 The variation of turbidity profiles measured by the water quality meter at the buoy.

of the scatterers in the water column below 10 m. Variations in suspended sediment concentrations may change the absorption of the acoustic signal with range leading to underprediction of the turbidity close to the bottom.

The degree of relationship between two variables, SNR measurements provided by ADCP and turbidity

measurements provided by WQC, was investigated through correlation coefficient as follows (Equation 4):

$$correl(x,y) = \frac{\sum (x - \bar{x})(y - \bar{y})}{\sqrt{\sum (x - \bar{x})^2 \sum (y - \bar{y})^2}} \quad (4)$$

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 7 Profiles of ADCP backscatter and suspended sediment concentration measured synchronously at a buoy on (a) 28 September 2006 and (b) 17 October 2006.

where x and y denote SNR and turbidity measurements respectively. The correlation coefficient was calculated for each data set and averaged to a single number. When only the water column above the thermocline was considered, the correlation coefficient was calculated as 0.85, and this number decreased to 0.65 when the whole water column was considered in the calculation. The best match was obtained on 28 September 2006 measurements. Considering only measurements on that date, the estimation equation is given below (Equation 5) ($R^2 = 0.83$):

$$SSC(estimated) = 0.3 \times SNR - 5, 2 \quad (5)$$

Effect of particle size

Acoustic frequencies have different sensitivities to particle size. Theoretically, the best results are obtained when $r * k = 1$, where r is the radius of the particle, and k is the acoustic wave number ($2\pi/\lambda$). For the current study, the corresponding acoustic wavelength λ is equal to 1 mm for the ADCP used and the best sensitivity expected for particle radius is close to 160 μm . Scattering strength of the equipment is provided by a simple model (SonTek, 1998) as shown in Figure 8. As can be seen in the figure, scattering strength decreases rapidly for particles smaller than 160 μm . Typical minimum particle size to be detected was 8 μm for the ADCP used in this study.

In order to determine the particle size distribution in the study site, soil samples were taken, and composite tests using both sieving and sedimentation methods were carried out. The air-dried sample of the soil is passed through different-size sieves, and the particles less than 0.075 mm were subjected to settle under gravity. Given by Stokes' Law, a falling particle reaches its terminal velocity that is proportional to the particle diameter. From the measurements at known time intervals, the distribution of particle size can be assessed. Based on this principle, hydrometer analysis was conducted in the lab for small particles. Particle size distribution of the samples collected at the banks of the Tahtali Lake is given in Figure 9. According to the results, soils of the study site can be described as sandy silt where more than 50% of the sample is finer than 0.075 mm; 28% of the soils are out of the detectable size of 8 μm .

The changes in SNR data were attributed to changes in suspended sediment concentration rather than to changes in particle size distribution since the mean percentage of the material collected at the study site was less than 100 μm 90% of the time as obtained from the sieve analysis.

Discussions and conclusions

Comparison of particulate matter quantity as received by the use of ADCP system and measured with

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 8 Variation of scattering strength of the equipment with particle size (From SonTek, 1998).

Suspended Sediment Concentration in Stratified Lakes Estimated by Acoustic Methods, Figure 9 Results of the sieve analysis of the soil sampled in the study site.

multiparameter water quality meter was presented in the current study. Focus was given to stratified environments since previous studies lack observations in the stratified lakes. Results of this study showed that ADCPs can predict the suspended sediment concentration within the thermocline. However, below the thermocline, they failed to predict the formation. This can be explained by the effect of suspended sediment concentration variations on the absorption of the acoustic signal.

The limitation of this methodology, the incapability of ADCPs to differentiate between changes in concentration and changes in particle size distribution, was partly overcome by analyzing the soil samples taken from the study site and describing their particle size distributions. Samples taken from the study site indicated that the mean percentage of the material collected at the study site was less than 100 μm 90% of the time. Further research in different stratified lakes in different environments are required to assess whether the changes in SNR data are attributed to changes in suspended sediment concentration or to changes in particle size distribution.

This method would be beneficial especially in the sediment transport studies, since ADCPs are capable of

measuring time series of vertical water profiles, thus providing much more information for sediment structure as compared with the point measurements made with conventional turbidity meters.

Acknowledgments

Equipment used in this study is provided from the research grants of the European Commission within the project No: 028292 (RESTRAT). I also would like to thank graduate students Anil Çalışkan and Ramazan Aydın and staff of Izmir Water and Sewage Authority (IZSU) for their contributions during the collection of data.

Synonyms

Major lakes in Sweden

Definition

Sweden's great lakes. The four largest lakes in Sweden with regard to surface area are, in order, Vänern, Vättern, Mälaren, and Hjälmaren. Vänern is the third largest lake in Europe after Ladoga and Onega in Russia, and Vättern is the 11th largest lake. On a global ranking, Vänern is the 33rd and Vättern the 78th largest lake in the world (Herdendorf, 1982).

Introduction

Sweden has close to 100,000 lakes, where a lake is defined as a water body with a surface area greater than 0.01 km² (Lindkvist and Danielsson, 1987). Approximately 9% of the area of Sweden constitutes lakes, which corresponds to a total lake surface area of about 40,000 km². In total, 22 lakes have a surface area of more than 100 km², 358 lakes an area between 10 and 100 km², and 3,990 an area between 1 and 10 km². The ten largest lakes with regard to surface area, together with their volume and mean and maximum depths, are given in Table 1 (the exact numbers can vary somewhat since many lakes are regulated). The

Sweden's Great Lakes, Table 1 The ten largest lakes in Sweden according to surface area together with lake volume and mean and maximum water depths (* indicates lack of data; mainly after Lindkvist and Danielsson, (1987))

Lake name	Surface area (km ²)	Volume (km ³)	Mean depth (m)	Maximum depth (m)
Vänern	5,648	153	27	106
Vättern	1,912	77.6	41	120
Mälaren	1,140	14.3	13	66
Hjälmaren	484	3.0	6	20
Storsjön	464	8.0	17	74
Torneträsk	330	17.1	52	168
Siljan	290	8.1	28	134
Uddjaure	252	*	*	*
Hornavan	250	11.9	46	221
Akkajaure	242	*	*	92

deepest lake in Sweden is Hornavan with a maximum depth of 221 m and a surface area of 250 km². This lake, which is located in the very north of Sweden where all the deepest lakes are found, is the third largest with regard to volume, but only the ninth largest if the surface area is considered.

Besides being important parts of the ecosystem, the lakes in Sweden are often utilized in a variety of human activities (Willen, 2001). Lakes are used for water supply both in municipal and industrial applications, as well as in irrigation occasionally. Their recreational value is substantial, supporting the local economy through the tourism they generate and sustain. Historically, early settlements developed at the major lakes because they provided opportunities for fishing and transportation, which in turn promoted trade and economic growth. As the urban areas rapidly developed in the nineteenth and early twentieth century, the lakes functioned as receiving waters for a wide range of pollution discharge, mostly untreated wastewater. In the 1950s, the pollution levels in many lakes were becoming a problem and treatment plants were introduced to remove pollutants in the wastewater before release to the lakes (Persson et al., 1989). The continuous expansion of treatment plants with increasing sophistication, where more and more of the pollutants are being removed, has to a large degree restored the initial water quality of the lakes.

Many lakes in Sweden have been formed in depressions associated with fault lines or uneven deposition of material in connection with the melting of the ice cap that covered Scandinavia during the latest glaciation. Thus, tectonic movement together with effects related to glaciation has determined morphometric properties of the lakes that to a large degree control different lake processes such as *circulation*, *stratification*, through-flow, and lake *mixing* and residence time. During the melting of the ice cap (deglaciation), large amount of water was released, simultaneously, as sediment transported with the water was deposited downstream the ice margin. Subsequently, after the ice cap melted, the land mass that was depressed

by the ice experienced a rebound (an uplift) creating a vertical shift of the land relative to the sea level. This rebound is still going on in Sweden today and it has been of great significance for the development of the lakes (Bengtsson, 1984).

The water *circulation* in the lakes, and the associated *mixing*, is affected by different *hydrodynamic* processes, including water inflow, convective currents from temperature differences, wind, and *seiching* (Rubin and Atkinson, 2001). Water inflow tends to have only local effects with little implications for the basin-scale motion. In contrast, convective currents resulting from seasonal changes in the heat transfer between the lake surface and the atmosphere initiate motion on the scale of the lake. Most Swedish lakes that are not shallow are subject to thermal *stratification* in the summer followed by complete *mixing* in the fall as the temperature drops in the atmosphere. Also, in the winter, lakes may become ice-covered, especially in Northern Sweden, again leading to *stratification* with the occurrence of complete *mixing* during the ice breakup in the spring (Bengtsson and Svensson, 1996).

The wind induces large-scale *circulation* as it blows over the water surface, creating shear stresses that initiate water motion in the downwind direction. Simultaneously, surface waves are generated that may grow to substantial heights, if the lake area is large. In Sweden, large waves are typically found in Vänern and Vättern, where fetch lengths (i.e., the distance the wind blows over to build up waves) are the greatest. Besides inducing a drift at the water surface, the wind causes a tilt in the mean water level with increasing deviation from the still water level in the downwind direction. In a stratified lake, this displacement of the water surface causes an associated tilt in the thermocline, several orders of magnitude greater. *Seiching* may be induced, at the water surface or the thermocline, if the lake water surface is inclined and the wind stops blowing.

The four largest lakes in Sweden are Vänern, Vättern, Mälaren, and Hjälmaren (see Figure 1). Together they have a surface area corresponding to almost 25% of the total lake surface area in Sweden. The four lakes are more or less distributed around a straight line from Stockholm on the east coast of Sweden to Gothenburg on the west coast. During the deglaciation, a connection existed along this line between the Baltic Sea and the North Sea during several periods (Björck, 1995). The Baltic Sea discharged its water to the North Sea through this connection, which appeared about 9,000–11,000 years ago, and it had a great influence on the properties of these lakes.

In the following, the main characteristics of the four largest lakes are briefly presented with focus on the morphometry and hydrology, as well as the major processes governing the *circulation* and *stratification* in the lakes. Table 2 summarizes key hydrological data for the four lakes according to Kvarnäs (2001).

Lake Vänern

Vänern is the largest lake in Sweden with a surface area of 5,648 km², a mean depth of 27 m, and a total volume of 153 km³. The inflow to Vänern originates from the largest catchment in Sweden encompassing almost 47,000 km², that is, more than 10% of the area of Sweden, although some part of the catchment is located in Norway. The outflow occurs through the Göta River providing the largest mean flow rate (about 500 m³/s) for any river in Sweden. Based on the lake volume and the through-flow, the lake residence time has been calculated to be approximately 10 years (Kvarnäs, 2001). Vänern consists of two subbasins that are separated by a shallow area containing a multitude of islands, which markedly influences the dynamics of the water *circulation* in the lake. The lake was regulated in the middle of the 1930s for hydropower purposes.

Sweden's Great Lakes, Figure 1 Map over the location of the four largest lakes in Sweden.

Sweden's Great Lakes, Table 2 Key hydrological data for Sweden's great lakes (mainly after Kvarnäs, 2001)

	Vänern	Vättern	Mälaren	Hjälmaren
Drainage area (km ²)	46,830	6,359	22,603	4,053
Surface runoff (l/s/km ²)	11.6	6.6	7.4	6.6
Outlet flow (m ³ /s)	516	42	168	27
Residence time (years)	9.8	58	2.8	3.7
Water level amplitude (m)	1.7	0.28	0.95	0.6
Precipitation (mm)	631	510	533	502
Evaporation (mm)	541	442	470	502

Direct precipitation on the lake corresponds to about 25% of the inflow from the catchment, and the river Klarälven contributes with 35% of the inflow. The Vänern catchment is located in a region where snow is common during the winter, leading to a marked peak in the runoff during the spring when the accumulated snow is melting. However, all the major rivers discharging into the lake are regulated, implying that the flow peak is attenuated in time.

Vänern is large enough to be influenced by the rotation of the earth. Thus, wind-induced currents may be affected by the Coriolis force, leading to a geostrophic *circulation* in the counterclockwise direction (Lindell and Welch, 1992). If the lake is stratified, this *circulation* also causes the thermocline to deform from its horizontal level. Geostrophic *circulation* has not been observed in any of the other large Swedish lakes, probably because of size, geometry, and shoreline configuration.

Thermal *stratification* occurs annually in Vänern, primarily in the summer. In August, the depth to the thermocline in the lake is about 15 m (mean depth 27 m). During some years, Vänern becomes completely ice-covered, but typically it is only in the coastal areas where ice develops. In the spring, a special type of horizontal *stratification* in the shallow areas known as a *thermal bar* may occur (Malm et al., 1998). Water in the shallow parts of the lake is heated up more quickly than the deeper parts and a vertical barrier (bar) between 4-deg water in the deeper parts and warmer water in the shallow parts emerges. This barrier moves offshore as the heating continues in the shallow parts. The *thermal bar* is typically present during a month (Kvarnäs, 2001). When the lake becomes completely ice-covered, slow-moving currents may still develop, although the effects of wind are absent (Bengtsson, 1996).

Lake Vättern

Vättern is the second largest lake in Sweden with a surface area of 1,912 km², a mean depth of 41 m, and a total volume of 78 km³. The catchment supplying water to Vättern is 6,359 km², implying that the ratio between the catchment area and the lake surface area is 3.3, which is

considerably smaller than for the other large lakes. Thus, the annual volume of direct precipitation on the lake surface is almost equal to the inflow. Vättern has an elongated shape with only one basin and relatively few islands, and the lake is oriented in the SSW-NNE direction with a maximum length of about 130 km. The lake was regulated in the late 1930s.

The annual mean flow through the lake is small with respect to the lake volume, resulting in a residence time that is rather long (58 years) compared to other Swedish lakes. Thus, seasonal or annual variations in the inflow to Vättern have limited effects on the water quality, since it takes considerable time before the inflow can contribute a runoff volume comparable to the lake volume. The main inflow is through the Huskvarna River and an adjacent smaller lake system, whereas the outflow occurs via Motala River to the Baltic Sea.

Seiching has been observed in Vättern and the period of the lowest mode is estimated to be about 180 min with maximum amplitude of 13 cm (Norrman, 1964). Subsequent studies have shown the presence of higher-order modes with periods of 98 and 81 min (Björk and Lundberg, 1990). Internal *seiching* in the thermocline also occurs where vertical movement of 15 m is possible at the ends of the lake (Kvarnäs, 2001). Strong winds may generate short-period surface waves of significant heights because of the relatively long fetch in the longitudinal direction of the lake. Theoretically, the significant wave height has been estimated to be over 2.0 m for wind speeds at 21 m/s (Norrman, 1964). The waves are often steep, that is, the wave height is large with respect to the wavelength, which could cause problems for boats.

Similar to Vänern, Vättern is seldom ice-covered during the winter, except in the coastal areas, and vertical *stratification* with a distinct thermocline primarily develops during the summer. In August, the depth to the thermocline is about 16 m (mean depth 40 m). The epilimnion (upper layer) temperature in Vättern is the lowest among the four largest lakes (just below 12°), since deeper lakes have larger heat storage capacity, implying a slower heating up (and cooling down).

Lake Mälaren

Mälaren is the third largest lake in Sweden with a surface area of 1,140 km², a mean depth of 13 m, and a total volume of 14 km³. The Mälaren catchment is almost 20 times larger than the lake surface area, which is the largest ratio among the great lakes of Sweden (e.g., the corresponding ratio for Vänern is 8.3). Mälaren has a complicated shoreline configuration since it was created through a number of faults generating fissures in the north-south direction. Thus, it is possible to identify five subbasins that have emerged as a result of tectonic movement and glacial processes (Kvarnäs, 2001), and the lake contains a large number of islands. Mälaren was first regulated in the beginning of the 1940s, and an important aim of the regulations has been to avoid saltwater intrusion from the Baltic Sea at low lake levels.

Having the largest catchment with respect to the lake surface area, direct precipitation on the lake surface has only a minor effect on Mälaren. The precipitation is about 10% of the inflow from the catchment. Mälaren is almost ice-covered every year and because of the thermal *stratification* that develops during the winter, oxygen deficit occurs in some parts of the lake. The *stratification* in the summer results in a thermocline that is located at 12 m water depth in August. Mälaren was the first Swedish major lake where water quality sampling was carried out in a systematic and comprehensive manner. This sampling was performed in the mid-1960s. After some years, water quality studies were also initiated in Hjälmaren and Vättern, followed by Vänern in the early 1970s (Willen, 2001).

Lake Hjälmaren

Hjälmaren is the fourth largest lake in Sweden with a surface area of 484 km², a mean depth of 6 m, and a total volume of 3 km³. The ratio between the catchment area and the lake surface area is 8.4, which is similar to Vänern. The lake has five subbasins with a number of fault zones extending in the east–west direction, with the northern part of the lake having a multitude of islands (Kvarnäs, 2001). The water that exits Hjälmaren enters into Mälaren trough Eskilstuna River, providing about 35% of the input flow to Mälaren. Hjälmaren was regulated at the end of the nineteenth century with the purpose of generating more agricultural areas. This led to a general decrease in the mean water level of about 1.3 m.

Hjälmaren is also ice-covered during most winters, whereas the limited water depth typically prevents development of a thermal *stratification*, even during the summer.

SWEDISH GLACIAL LAKES: ESTIMATION OF THE NUMBER OF LAKES OF DIFFERENT SIZES

Lars Håkanson

Department of Aquatic Sciences and Assessment,
 Institute for Water and Environment, Swedish University
 of Agricultural Sciences, Uppsala, Sweden

Introduction and Aim

How many lakes are there in Sweden? Such seemingly nonsensical questions are discussed in the scientific literature. But what is the relevance of the question? It may very well be nonsensical from many perspectives but not if one would like to use such estimates to determine the breeding grounds for toads, mosquitoes, beavers, or wild orchids. The basic aim of this section is to provide an estimate of the total number of lakes in Sweden. The method to do this concerns transformations, regressions, and extrapolations (Håkanson and Peters, 1995).

Major lake types on earth

Practically all lakes in Sweden have been influenced by the enormous form-creating power of the latest glaciation. All these lakes will, in due course, be filled up and vanish. Hutchinson (1957) has discussed all major lake types, their origin, morphometric characteristics, and distribution on Earth. He differentiated between 11 major lake types that were divided into 76 subtypes. The 11 major lake types are summarized in Table 1. Most lakes on Earth appear in glacial landscapes.

Swedish Glacial Lakes: Estimation of the Number of Lakes of Different Sizes, Table 1 Major lake types on Earth according to Hutchinson (1957)

1. Tectonic lakes, e.g., basins in faults (like Lake Bajkal and Lake Tanganyika).
2. Volcanic lakes, e.g., maars, caldera lakes and lakes formed by damming of lava flows.
3. Landslide lakes, e.g., lakes held by rockslides, mudflows, and screes.
4. Glacial lakes:
 - A. lakes in direct contact with ice, e.g., lakes on or in ice and lakes dammed by ice.
 - B. Glacial rock basins, e.g., cirque lakes and fjord lakes.
 - C. Morainic and outwash lakes, e.g., lakes created by terminal, recessional, or lateral moraines
 - D. Drift basins, e.g., kettle lakes and thermokarst lakes.
5. Solution lakes, e.g., lakes formed in caves by solution.
6. Fluvial lakes:
 - A. Plunge-pool lakes.
 - B. Fluvial dams, e.g., strath lakes, lateral lakes, delta lakes and meres.
 - C. Meander lakes, e.g., oxbow lakes and crescentic levee lakes.
7. Aeolian lakes, e.g., basins dammed by wind-blown sand and deflation basins.
8. Shoreline lakes, e.g., tombolo lakes and spit lakes.
9. Organic lakes, e.g., phytogenic dams and coral lakes.
10. Anthropogenic lakes, e.g., dams and excavations made by man.
11. Meteorite lakes, e.g., meteorite craters.

Number of lakes in Sweden

The geographical distribution of all the Swedish lakes is shown in Figure 1. It is evident that the country of Sweden in many ways has its character from these many lakes. This is true also in many other countries dominated by glacial lakes, e.g., Finland, northern Russia, Canada, and northern U.S.A.

Table 2 divides the lakes in Sweden into different classes according to lake area (there are 3 lakes larger than 1,000 km²: Vänern, Vättern, and Mälaren; 19 lakes between 100 and 1,000 km², etc.). The data given in Table 2 have been used to illustrate the relationship between lake area and number of lakes (Figure 2a): There is a clear, logical quantitative relation between lake size and the number of existing lakes in the given size categories.

By making different types of transformations of the x- and y-parameters in this plot, it is possible to obtain a very good linear regression. This is shown in Figure 2b, which gives area^{0.05} on the x-axis and cumulative number (Cum. number^{0.1}) on the y-axis. The r²-value (the coefficient of determination) is 0.999. The regression line is: $y = -3.834 \cdot x + 6.147$. Many different types of transformations and exponents have been tested for the x- and y-parameters. From this, one can estimate the number of lakes in Sweden larger than 0.1 ha in area. This extrapolation (Figure 2b) suggests that 227,000 such lakes exist in

Swedish Glacial Lakes: Estimation of the Number of Lakes of Different Sizes, Figure 1 Lakes in Sweden larger than 1 km². The map was kindly provided by SMHI (Swedish Meteorological and Hydrological Institute).

Swedish Glacial Lakes: Estimation of the Number of Lakes of Different Sizes, Table 2 The number of lakes in Sweden arranged by size (Håkanson and Peters, 1995)

Area (1 km ² = 100 ha)	Number	Cumulative number
>1,000	3	3
100–1,000	19	22
10–100	362	384
1–10	3,987	4,371
0.1–1	19,374	23,745
0.01–0.1	59,500	83,245
0.001–0.01	144,000	227,000

Sweden. One can also estimate that there exist about 520,000 lakes and ponds larger than 100 m².

It is also easy to estimate the total area of these lakes from the number of lakes within a given size class and the mean (or median) area of the size class.

Despite its high r², this relationship, like all empirical relationship, is only valid for lakes of this type, i.e., glacial

Swedish Glacial Lakes: Estimation of the Number of Lakes of Different Sizes, Figure 2 (a) Relationship between lake area and number of lakes in Sweden in the given size classes. (b) A regression between lake area ($\text{area}^{0.05}$) and cumulative number of lakes in Sweden in the given size classes ($\text{Cum. number}^{0.1}$). The r^2 -value is 0.999. The number of lakes in Sweden larger than 0.1 ha is estimated to be 227,000 from this plot.

Swedish Glacial Lakes: Estimation of the Number of Lakes of Different Sizes, Table 3 Morphometrical data for the four largest Swedish lakes (From Håkanson, 1979)

	Vänern	Vättern	Mälaren	Hjälmaren
Total area (km ²)	5,893	1,898	1,617	492.9
Open water area (km ²)	5,648	1,856	1,096	477.8
Volume (km ³)	153	74.0	14.0	2.89
Maximum depth (m)	106	128	63	22.0
Mean depth (m)	27.0	39.8	12.8	6.05
Large islands (>1 km ²), number	20	6	43	4
Total area (km ²)	177.8	36.2	9.03	9.03
Islands (1–0.01 km ²); number	793	81	354	95
Total area (km ²)	54.7	4.65	4.51	4.51
Small islands (1–0.01 ha); number	8,772	813	1,248	963
Total area (km ²)	11.8	0.96	1.21	1.21
Rocks (<0.01 ha); number	12,100	10,999	6,584	14,546
Total area (km ²)	0.58	0.52	0.31	0.36

lakes (see Table 1). One could guess that similar results would be obtained for other parts of the world influenced by glacial activity. Such lakes are by far the most common lake type on Earth.

Islands in glacial lakes

Table 3 gives key morphometrical data for the four largest Swedish lakes: Vänern (which is the fourth largest lake in Europe), Vättern, Mälaren, and Hjälmaren and the table

also gives the number of islands in these glacial lakes. One can note that there are more than 20,000 islands (and rocks) in Lake Vänern. Also note the clear relationship between size and number of islands in the lakes: There are relatively few large islands with a relatively large total area and there are many small islands and rocks with a relatively small total area. This relationship between size and number is typical for lakes from glacial landscapes.

Introduction

Lake Tanganyika is one of the Great Rift Valley Lakes of East Africa (Figure 1) and is situated between 3°S and 9°S. It is 650 km long with a mean width of around 50 km and an average depth of 570 m. It is a freshwater Lake characterized by a quasi-permanent thermocline. The Lake is meromictic – complete overturning of the water never takes place – and mixing occurs only partially. The epilimnion (surface layer) undergoes seasonal temperature change annually, while the hypolimnion is anoxic with an invariant temperature. The hypolimnion is a vast reservoir of nutrients largely isolated from surface influences (Hecky and Fee, 1981; Hecky et al., 1991). The average transparency of the Lake is close to 11 m. The solar radiation around the Lake varies very little in the year because of its closer proximity to the equator. The nutrients supplied to the mixed layer, where photosynthesis can occur, are mainly internal nutrients from within the Lake, whereas riverine and atmospheric input of nutrients is considered negligible for Lake Tanganyika (Hecky and Fee, 1981; Sarvala et al., 1999a; Langenberg et al., 2003a). Nutrients from the hypolimnion are supplied to the epilimnion mainly by wind-driven upwelling of the strong southeast winds during the dry season from March/April

until August/September (Hecky et al., 1991; Plisnier et al., 1999; Langenberg et al., 2003b). The wind stress pushes the warmer surface water away from the southern end of the Lake toward the northern end, resulting in a well-known compensating upwelling in the south. This upwelling results in the seasonal enhancement of the nutrients in the euphotic layer initiating phytoplankton blooms. Apart from this major wind-induced southern upwelling, small coastal upwellings can also be seen from time to time propagating clockwise around the western boundaries of the lake, which are the internal Kelvin wave packets (Naithani and Deleersnijder, 2004). During the wet season, the primary production is less important and is primarily dependent on the nutrients regenerated within the epilimnion (Coulter and Spigel, 1991).

The above mentioned thermodynamic, hydrodynamic, and ecological characteristics are incorporated into an eco-hydrodynamic model to study the primary food web of Lake Tanganyika. The hydrodynamic model comprises nonlinear, reduced-gravity equations (Naithani et al., 2002, 2003). The ecological model components include one nutrient, phytoplankton biomass, zooplankton biomass, and detritus (Naithani et al., 2007a, b, 2011).

Materials and method

The model consists of a four-component ecosystem model, coupled to a hydrodynamic model. The hydrodynamic model considers the Lake as two homogeneous layers of different density lying above each other, representing the warm epilimnion (surface mixed layer) and cold dense hypolimnion (lower layer) separated by a thermocline (Naithani et al., 2002, 2003). The lower layer is considered to be much deeper than the surface active/mixed layer. The model is forced with the wind and solar radiation data from the NCEP reanalysis. Studies using the hydrodynamic model have shown that in the motion of water there are internal waves with oscillations similar to that in the forcing

Tanganyika Lake, Modeling the Eco-hydrodynamics, Figure 1 Geographic map of Lake Tanganyika.

winds (Naithani et al., 2002, 2003). The simulated oscillations compare satisfactorily with those derived from observed temperature in the Lake (Naithani et al., 2002, 2003). The coupled ecological-hydrodynamic model simulations show also good correspondence with the measurements from the Lake (Naithani et al., 2007a, b).

The hydrodynamic model equations are:

$$\frac{\partial \xi}{\partial t} + \frac{\partial(Hu)}{\partial x} + \frac{\partial(Hv)}{\partial y} = w_e \quad (1)$$

$$w_e = \left(\frac{3}{20}\right)^{1/2} \frac{(\tau_x^2 + \tau_y^2)^{1/2}}{(\varepsilon g H)^{1/2}} - w_d - \frac{\xi}{r_{tt}} \quad (2)$$

$$\begin{aligned} \frac{\partial(Hu)}{\partial t} = & -\frac{\partial(Huu)}{\partial x} - \frac{\partial(Hvu)}{\partial y} + fHv - gH \frac{\partial \xi}{\partial x} \\ & + \frac{\partial}{\partial x} \left(HA_x \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left(HA_y \frac{\partial u}{\partial y} \right) + \frac{\tau_x}{\rho_0} + w_e^- u \end{aligned} \quad (3)$$

$$\begin{aligned} \frac{\partial(Hv)}{\partial t} = & -\frac{\partial(Huv)}{\partial x} - \frac{\partial(Hvv)}{\partial y} - fHu - gH \frac{\partial \varepsilon \xi}{\partial y} \\ & + \frac{\partial}{\partial x} \left(HA_x \frac{\partial v}{\partial x} \right) + \frac{\partial}{\partial y} \left(HA_y \frac{\partial v}{\partial y} \right) + \frac{\tau_y}{\rho_0} + w_e^- v \end{aligned} \quad (4)$$

where x and y are horizontal axes, u and v are the depth-integrated velocity components in the surface layer in the x and y directions, t is the time, x is the downward displacement of the thermocline, $H = h + \xi$ is the thickness of the epilimnion (the surface, well-mixed layer), h is the reference depth of the surface layer (m), and w_e is the entrainment velocity (ms^{-1}). The first term on the right hand side of Equation 2 is inspired by Price (1979), τ_x and τ_y are horizontal components of specific wind stress in the x and y direction (m^2s^{-2}), and $\varepsilon = (\rho_b - \rho_s)/\rho_b$ is the relative density difference between the hypolimnion (ρ_b) and the epilimnion (ρ_s), calculated using the temperature of the surface layer (t_s) and bottom layer (t_b) respectively. w_d is the detrainment term (ms^{-1}), defined such that the annual mean of the epilimnion volume remains approximately constant. There are large uncertainties in the parameterization of entrainment and detrainment terms. As a consequence, to avoid occasional spurious values of ξ , a relaxation term (ξ/r_{tt}) is needed which slowly nudges the surface layer depth toward its equilibrium position. The relaxation timescale, r_{tt} , is sufficiently long so that the relaxation term is generally smaller than the entrainment and detrainment terms. f is the Coriolis factor (<0 in the southern hemisphere), and A_s is the horizontal eddy viscosity in the s ($=x,y$) direction.

The ecosystem model (Figure 2) consists of dissolved phosphorus (*Phos*), phytoplankton (*Phyto*), zooplankton (*Zoo*), and detritus (*Detr*) (Naithani et al., 2007b). Phosphorus was the only nutrient simulated in the model to trigger phytoplankton growth (Järvinen et al., 1999). The phytoplankton processes include primary production (*PROD*), respiration (*RESP*), and mortality (*MORT_a*). The processes concerning the zooplankton are grazing (*GRAZ*), fecal pellet (*FEC*) egestion, excretion (*EXC*), and mortality (*MORT_z*). Phytoplankton respiratory release and the excretion from zooplankton are directly remineralized in the surface layer. A small percentage of feces, dead phytoplankton, and zooplankton are also remineralized into phosphate in the surface layer whereas the rest contributes to the detritus pool, which sediments fast. The regeneration/remineralization within the surface layer represents the effect of the microbial food web and also represents the pelagic regeneration. The model is closed by predation (*PRED*) from zooplanktivorous fish and sinking of detritus out of the surface layer. The zooplanktivorous fish biomass is assumed equal to that of zooplankton biomass (Sarvala et al. 1999a).

The ecosystem model equations are:

$$\begin{aligned} \frac{\partial(H\text{Phyto})}{\partial t} = & -\frac{\partial(Hu\text{Phyto})}{\partial x} - \frac{\partial(Hv\text{Phyto})}{\partial y} \\ & + \frac{\partial}{\partial x} \left(HK_x \frac{\partial \text{Phyto}}{\partial x} \right) + \frac{\partial}{\partial y} \left(HK_y \frac{\partial \text{Phyto}}{\partial y} \right) + \phi_{he} \\ & + H\{\text{PROD} - \text{RESP} - \text{MORT} - \text{GRAZ}\} \end{aligned} \quad (6)$$

$$\text{PROD} = r_p \min[2F(I), F(P)]\text{Phyto} \quad (7)$$

Tanganyika Lake, Modeling the Eco-hydrodynamics, Figure 2 Flow diagram of the ecological parameters considered in the model.

$$RESP = r_a r_p \min[2F(I), F(P)]Phyto \quad (8)$$

$$MORT_a = m_a Phyto \quad (9)$$

$$GRAZ = r_z \frac{Phyto}{Phyto + k_{phyto}} Zoo \quad (10)$$

$$F(P) = \frac{Phos}{Phos + k_{phos}} \quad (11)$$

$$F(I) = (1/k_e H) [\arctan(\alpha I_0 / 2I_k) - \arctan(\alpha I_0 e^{-k_e H / 2.1_k})] \quad (12)$$

$$k_e = 0.066 + 0.07 \frac{Phyto}{r_c} \quad (13)$$

$$\phi_{he} = w_e^+ Phyto_h + w_e^- Phyto \quad (14)$$

$$\begin{aligned} \frac{\partial(HZoo)}{\partial t} = & -\frac{\partial(HuZoo)}{\partial x} - \frac{\partial(HvZoo)}{\partial y} \\ & + \frac{\partial}{\partial x} \left(HK_x \frac{\partial Zoo}{\partial x} \right) + \frac{\partial}{\partial y} \left(HK_y \frac{\partial Zoo}{\partial y} \right) + \phi_{he} \\ & + H \{ GRAZ - EXC - FEC - MORT_z - PRED \} \end{aligned} \quad (15)$$

$$EXC = n_e GRAZ \quad (16)$$

$$FEC = n_f GRAZ \quad (17)$$

$$MORT_z = m_z GRAZ \quad (18)$$

$$PRED = r_f \frac{Zoo}{Zoo + k_{zoo}} Fish \quad (19)$$

$$\begin{aligned} \frac{\partial(HPhos)}{\partial t} = & -\frac{\partial(HuPhos)}{\partial x} - \frac{\partial(HvPhos)}{\partial y} \\ & + \frac{\partial}{\partial x} \left(HK_x \frac{\partial Phos}{\partial x} \right) + \frac{\partial}{\partial y} \left(HK_y \frac{\partial Phos}{\partial y} \right) \\ & + \phi_{he} + H \left\{ \frac{-(PROD - RESP)}{CP_a} + \left(\frac{p_a MORT_a}{CP_a} \right. \right. \\ & \left. \left. + \frac{(p_f FEC + p_z MORT_z + EXC)}{CP_z} \right) \right\} \end{aligned} \quad (20)$$

$$\begin{aligned} \frac{\partial(HDetr)}{\partial t} = & -\frac{\partial(HuDetr)}{\partial x} - \frac{\partial(HvDetr)}{\partial y} \\ & + \frac{\partial}{\partial x} \left(HK_x \frac{\partial Detr}{\partial x} \right) + \frac{\partial}{\partial y} \left(HK_y \frac{\partial Detr}{\partial y} \right) + \phi_{he} \\ & + H \{ (1 - m_p) MORT_a + (1 - p_f) FEC \\ & + (1 - p_z) MORT_z - r_d Detr \} - w_d Detr \end{aligned} \quad (21)$$

The first four terms on the right hand side of Equations 6, 15, 20, and 21 represent the horizontal advection and diffusion of the ecological parameters, u and v are time-dependent horizontal velocities obtained from the circulation model, and K_x and K_y are the horizontal

diffusion coefficients. The fifth term represents entrainment from hypolimnion. Entrainment of phosphate from the hypolimnion was extrapolated exponentially from $45 \mu\text{gPL}^{-1}$ below 60 m depth to $1 \mu\text{gPL}^{-1}$ near the surface (Coulter and Spigel, 1991; Plisnier et al., 1996; Plisnier and Descy, 2005). This ensured that the water is richer in nutrients if upwelling occurs from deeper depths. The definition of the parameters and their values are given in Table 1. Model was run with the thermocline at 30 m and the temperature of the surface and lower layers as 27°C and 24.5°C , respectively for the years 2002–2009.

Results and discussion

Figure 3 shows the time series of wind speed, model predicted surface layer (epilimnion) depth, and the depth-averaged concentration in the surface layer of phosphate, phytoplankton biomass, and zooplankton biomass. The surface layer depth increases at the beginning of the dry season because of wind driven mixing and remains at greater depth during the whole season. It decreases at the end of the dry season and remains more or less at this depth during the wet season until the beginning of the next dry season. Phosphate concentration closely follows the mixed layer depth. It increases because of entrainment associated to the upwelling of nutrients from below and remains high for the rest of the dry season, because of almost continuous upwelling, and decreases at the end of the dry season. Increase in the biomass of phytoplankton at the beginning of the dry season is natural because of the input of nutrients in the surface layer. However, the phytoplankton biomass cannot sustain at this high value and decreases in spite of the continuous abundance of nutrients. The increased surface layer depth caused by persistently higher winds forced the algal community to spend more time in deeper water with reduced light, thereby decreasing the productivity. Phytoplankton biomass shows another bloom at the end of the dry season when the SE wind diminishes and, subsequently, changes direction, and the surface layer still carrying adequate amounts of nutrients relaxes back to shallower depths (Plisnier et al., 1999). Phytoplankton biomass in effect showed a trade-off between the availability of nutrients and light. Negative effects of deep mixing on the phytoplankton biomass were also considered by Sarvala et al. (1999b).

Effect of changing the model ecological parameters

Increasing (decreasing) the half-saturation constant for grazing decreased (increased) the zooplankton biomass and increased (decreased) phytoplankton biomass (Naithani et al., 2007a). The change in the phytoplankton biomass is almost half the change in the zooplankton biomass. Decreasing the predator population increases the zooplankton biomass and vice versa. For these tests with the predator population the change in the phytoplankton biomass is much less than the change in the zooplankton biomass. It is seen that the primary production, which

strongly depends upon the light in the water column and entrainment of nutrients, is bottom-up controlled, while it seems that predator abundance strongly controls zooplankton biomass (top-down control, Naithani et al., 2007a). By contrast, fish predation influence seems reduced on the phytoplankton level. In other words, any change in predator biomass significantly affects the herbivore biomass, but has little influence on phytoplankton biomass. Indeed, in our simulations, reduced grazing pressure from top-down control of mesozooplankton did not increase phytoplankton abundance considerably. In planktivore-dominated Lake Tanganyika, zooplankton are not able to control phytoplankton, and therefore, light or nutrient limitation and resource competition seem to be common among the latter (Järvinen et al., 1999).

Effect of changing the physical parameters

Various tests of the model using different physical parameters (thermocline depth, surface layer temperature, and wind velocity) are summarized in Figure 4. Any change in these physical forcing parameters modifies the timing and intensity of the dry season blooms of the biogeochemical parameters (Naithani et al., 2011). Increasing t_s or the wind stress delays the phytoplankton peak. Increasing the reference thermocline depth (h) increases the entrainment of phosphate from below and decreases the phytoplankton biomass. Increasing/decreasing the surface layer temperature decreases/increases the depth of the upper mixed layer and the entrainment of phosphate (Naithani et al., 2011). This decreases the phytoplankton biomass. The phytoplankton growth is favored at low t_s for a shallower

Tanganyika Lake, Modeling the Eco-hydrodynamics, Figure 4 Lake averaged parameters for various h and t_s (a1–a4), for wind stress varying by the factor indicated in the ordinate and t_s , at $h = 30$ m (b1–b4), for various wind stress and h (c1–c4), and for various wind stress and t_s , at $h = 70$ m (d1–d4).

thermocline and high t_s at a deeper thermocline. Increasing wind stress favors phytoplankton production because of deeper mixing.

An increase in temperature will decrease the phytoplankton and zooplankton biomass. This is because high temperature will result in shallower thermoclines, thereby decreasing the mixing probabilities with the nutrient-rich bottom water (Livingstone, 2003; Verburg et al., 2003; Verburg and Hecky, 2009). Lower temperature will lead to deeper lying thermocline thereby forcing the algal community to spend more time in the low light conditions at greater depths. Decreasing wind stress also has a negative effect on the growth. However, if these high temperatures are accompanied by stronger winds, the resulting wind mixing will bring the nutrients up to the euphotic zone allowing a greater primary production.

Conclusions

The behavior of the model-simulated parameters reflects that the dominant components responsible for the phytoplankton biomass in the lake are temperature stratification, availability of light and nutrients. Primary production in the nutrient-depleted surface layer depends upon the recycling of nutrients by wind-induced vertical mixing. The transport and mixing events are critical for the resupply of nutrients for the primary productivity and biogeochemical processes in the stratified lake. Increasing stratification decreases mixing and entrainment of nutrients from the hypolimnion. At too high light conditions at shallower depths, linked to higher surface layer temperature, the phytoplankton growth was limited by nutrients. Inversely, at higher nutrient levels at deeper depth, associated with low surface layer temperature, phytoplankton production was limited by light. The most favoring surface layer depth for the biomass production was found to be between 40 and 60 m (Figure 4). This depth seems to be linked to optimal light and nutrient conditions allowing phytoplankton production and an increase in its biomass. High winds are important for the supply of nutrients to the euphotic zone in the Lake. They are also linked with increased internal wave activities and turbulence. This could induce an increased temporal patchiness in the primary production (short moments when primary production could be very high). So the average seasonal condition should not be considered when investigating phytoplankton growth. But short-term strong wind events could also be important for local blooms in phytoplankton.

It can be inferred that a slight increase in temperature will still be bearable for Lake Tanganyika ecosystem, as long as the wind is strong enough to mix water and bring nutrients from the hypolimnion to the epilimnion. Otherwise, the primary production will decrease.

Introduction

Lake Tanganyika (Figure 1) is one of the few ancient lakes in the world (estimated age 9–12 million years; Cohen et al., 1993). It is the second in size of the African Great Lakes and also second in depth among lakes in the world. It locates at an altitude of 773 m above m.sl. The drainage area is 263 000 km². The lake is 650 km long and 50 km wide in average. It has three main basins. In the north, the Kigoma basin extends to the depth of 1,310 m. The middle basin is separated from the Kigoma basin by a broad sill with a depth of 655 m, and in the south, from the Kipili basin by another sill with a depth of 700 m. The basin near Kipili is the deepest of the three basins, its maximum depth being 1,470 m. The lake is meromictic with stable hypolimnetic waters, and the salt content is low for this type of lake (Coulter, 1991).

The early studies from the beginning of the last century have been summarized by Coulter (1991). Later, a Belgian exploration in 1946–1947 proved the existence of internal waves in the thermocline as they measured the lake water temperature. Another result of the same expedition was the first bathymetric chart of the lake by Figure 1. In the late 1950s, Dubois collected the first depth-time series of temperature and oxygen data. In the early 1960s, Coulter (1963) continued the studies in the south, and later on, in 1973–1975, in the northern part of the lake.

Lake Tanganyika was studied intensively during 1990s as part of the Lake Tanganyika Research for the Management of Fisheries (LTR) by FAO and also as part of Lake

Tanganyika Biodiversity Project/LTBP by UNDP/GEF (www.fao.org/fi/ltr (LTR) and <http://www.ltbp.org/> (LTBP)). Water level fluctuations and meteorological data were collected at Bujumbura (Burundi), Kigoma (Tanzania), and Mpulungu (Zambia). Limited meteorological observations were conducted also in Uvira (DR Congo), Kalemie (DR Congo), and Kipili (Tanzania). Data on the thermal regime of the lake waters were collected with two moored buoy stations and also with a CTD-profiler near field stations, as well as from the research vessel during the expeditions. Data on water currents were collected with flow cylinders, which were used intensively near the field stations and also on lake-wide expeditions. During LTBP, also acoustic Doppler current profilers (ADCP) were used both on board and at moored stations.

Later four Finnish universities have arranged several field courses in Kigoma, Tanzania.

The CLIMLAKE “Climate Variability as Recorded by Lake Tanganyika,” funded by the Belgian Science Policy, included a 3-year survey of the lake over the period 2002–2004. Also hydrodynamic and ecological models were developed for the lake. The aim of the project was to understand the Lake Tanganyika variability and sensitivity to climate change. Another Belgian project, CLIMFISH was active in years 2004–2006.

Meteorological conditions

There are two main seasons with different weather conditions within the yearly cycle in the Lake Tanganyika region. The wet season from October to April is characterized by weak winds over the lake, high humidity, considerable precipitation, and frequent thunderstorms (Figure 2). The dry season from May until the end of August is characterized by little precipitation and strong, regular southerly winds. The seasonal changes of weather and winds result from large-scale atmospheric processes, especially of the position of the global tropical wind convergence zone.

The diurnal cycle of winds is also well developed in Tanganyika region. The studies of Savijärvi (1995 and 1997) and Podsetchine et al. (1999) revealed that the mountain slopes contributed about 50% and the trade winds 25% to the diurnal variation of winds. The rest 25% of the wind variation was due to the lake effect. The SE trade wind enhances the lake breeze considerably at daytime and adds on the downslope winds at nighttime.

Thermal regime

The seasonal thermal regime of the lake has been discussed by Capart (1952), Coulter (1963, 1991), Huttula (1997), Plisnier et al. (1999), Langenberg et al. (2002), Verburg et al. (2003), and Verburg and Hecky (2009).

Heating of the lake takes place mainly in the beginning of the wet season in October–November (Coulter, 1991; Huttula, 1997). Thermal stratification prevails all over the lake. The thermocline is situated at the depth of

Tanganyika Lake: Strong in Hydrodynamics, Diverse in Ecology, Figure 1 Bathymetric map of Lake Tanganyika.

40–60 m. The lake loses heat through evaporation caused by strong winds during the dry season (Coulter, 1991). This cooling is strongest in the southern basin. In the epilimnion, the temperature varies between 25°C in August

and 27°C in April. In the hypolimnion, the temperature varies only between 23.43 and 23.48°C.

During lake-wide expeditions in the 1990s, the water temperature data revealed a clear down-tilting of the

Tanganyika Lake: Strong in Hydrodynamics, Diverse in Ecology, Figure 2 Lake Tanganyika scenery on a calm sunny day in the wet season (Photo Jouko Sarvala).

thermocline (on an average 4 cm/km) in dry season from S to N along the main axis of the lake (Huttula, 1997). This corresponded with the findings of Coulter (1963, 1968) from more than 30 years earlier. Higher temperatures and deeper depth of certain isolines indicated increased heating of waters over the years. Also O'Reilly et al. (2003) have discussed the heating of the lake and decreasing wind speeds and consequent significant increase of lake water stability during the last century. The transverse eastward down-tilting was observed in the Kalemie strait both in the wet season and the dry season as high current speeds were observed. This tilting was obviously connected to the uninodal internal seiche in the lake.

Hydrodynamics

Upwelling in Lake Tanganyika has been observed at the very southern end of the lake during the dry season in May–August.

The stability of 70% of the lake volume and the great age of the lake should lead to a high depth gradient of salts. However, several studies show that no such gradient exists in the lake's deep waters, which indicates some kind of deep water circulation. Tietze (1982) estimated that the decrease in density due to temperature changes within the metalimnion was about 1 kg m^{-3} and that density variations due to dissolved substances were 5% of those due to temperature variations.

The most extensive hydrodynamic measurements were conducted during the LTR (Huttula, 1997). A uninodal surface seiche was observed with a period of 4.7 h with a phase shift of 180° between Bujumbura in the north and Mpulungu in the south. The observed uninodal internal seiche period at Mpulungu buoy was 23.4 days during dry season (Fig. 3). During wet season, the period was much longer, 34.8 days. At Kigoma buoy data allowed to determine the period only for wet season, when it was 26.3 days (Podsetchine and Huttula, 1996).

The vertical mixing conditions and stratification varied seasonally and from year to year, with strongest mixing

during the dry season. Interannual variation was seen in the years 1993–1996 off Mpulungu, where mixing intensity decreased for each successive year (Verburg et al., 1998).

High Resolution Limited Area atmospheric Model (HIRLAM) was used for driving the 3D lake flow and transport model and regional flow and sediment transport models near the Malagarasi river mouth, as well as in the Mpulungu bay (Huttula, 1997). Model validation was carried out for the wet season (April 1997) and dry season (August 1997). Several mesoscale gyres were observed in the lake. Diurnal variation of surface water currents was observed at several sites such as the shallow waters near Malagarasi, Rusizi, and even the deeper inlet area of Lufubu. The local lake-land breeze system highly dominated the short-scale current field in the lake. The seasonal variation of the current field was observed to act as superimposed on this local system. In the dry season, the discharge of the river waters and suspended particulate matter (SPM) concentration in river waters were low. The simulations showed that, at this time, the dilution and the advection of river waters happen in the vicinity of the river mouths. Gravitational settling, advective transport by wind-induced currents, and turbulent diffusion are the main governing factors generating the zones of higher suspended solids concentration mainly in shallow areas near river and creek outlets. The great depth of the lake reduces the probability of erosion and resuspension of settled solid particles to limited shallow areas near shoreline.

Naithani et al. (2007) proposed an eco-hydrodynamic (ECOH) model for Lake Tanganyika to study the plankton productivity. The hydrodynamic sub-model solves the nonlinear, reduced-gravity equations in which wind is the dominant forcing. The ecological sub-model for the epilimnion comprises nutrients, primary production, phytoplankton biomass, and zooplankton biomass. In the absence of significant terrestrial input of nutrients, the nutrient loss is compensated for by seasonal, wind-driven, turbulent entrainment of nutrient-rich hypolimnion water into the epilimnion, which gives rise to high plankton productivity twice in the year, during the transition between two seasons.

The pelagic ecological system is highly dynamic

Lake Tanganyika is home to more than 2,000 plant and animal species, a large number of them endemic. The fish community comprises 250 cichlid and 75 non-cichlid species, 98% and 60% of which, respectively, are endemic. Most of the diversity resides in the narrow littoral zone around the perimeter of the lake, while the pelagic food web, on which the fish production is mainly based, is extremely simple for a lake of this size (Coulter, 1991).

The pelagic ecosystem of Tanganyika is very patchy and dynamic, both physically and biologically. Limnological conditions and planktonic resources exhibit high spatial and temporal variability at various time scales (Descy et al., 2005; Bergamino et al., 2007).

Tanganyika Lake: Strong in Hydrodynamics, Diverse in Ecology, Figure 3 Water temperature isolines (°C) based on daily means. Period from March 1993 to May 1994 from Mpulungu buoy. (From Huttula, 1997.)

Phytoplankton production is to a large extent based on nutrients supplied from the anoxic hypolimnion through various mixing processes (Coulter, 1991). Accordingly, on short time scales, the dominant control on productivity is wind-driven, dry season upwelling, while in the long-term productivity is controlled by external loading determined by changes in precipitation (Langenberg et al., 2003; Cohen et al., 2006). Wind-driven gradual change in physical and chemical properties of the productive zone along the north–south axis creates regional variation in nutrient flows and plankton community structure and affects food web functioning (Coulter, 1991; Langenberg et al., 2008). Strong coupling of meteorological data and water column properties was also confirmed by Nahimana et al. (2008).

Planktonic copepods may show eight or more abundance peaks during a year (Mölsä et al., 2002). Both zooplankton and fish perform extensive diel vertical migrations (Coulter, 1991; Vuorinen et al., 1999), and variable horizontal aggregations are characteristic of the fish populations, particularly the schooling clupeid *Stolothrissa* (Plisnier et al., 2009). However, at longer time periods, at the scale of fish generation times (from about one to several years), the system appears rather stable (Sarvala et al., 2002). Lake Tanganyika, together with Lake Baikal, is the least disturbed and most pristine ecosystem of the Great Lakes of the world, although even Tanganyika is subject to anthropogenic threats, notably deforestation of the drainage basin, overfishing, and climate change (Dobiesz et al., 2010).

Trophic relationships

Food preferences of the pelagic fish have been analyzed from the stomach contents of freshly caught fish (Coulter,

1991; Mannini et al., 1999). Much less is known about the trophic relationships in the lower part of the pelagic food web, but recently, the trophic relationships have been clarified using stable isotope ratios of carbon and nitrogen in different components of the food web (Sarvala et al., 2003).

Most of the phytoplankton biomass is located in the 0–40 m layer, with maxima at 0–20 m, and more rarely at 40 m. Deep chlorophyll maxima and surface “blooms” (typically of *Anabaena*) are occasionally observed, particularly in October–November (Salonen et al., 1999). Phytoplankton community comprises up to about 200 species. The phytoplankton assemblage is dominated by chlorophytes and cyanobacteria, with diatoms (such as *Nitzschia*) developing mainly in the dry season (Hecky and Kling, 1981; Vuorio et al., 2003; Cocquyt and Vyverman, 2005; Descy et al., 2005). The dominant cyanobacteria are very small unicells (picocyanobacteria, mostly *Synechococcus*), more abundant in the southern basin, whereas green algae dominate in the north end (Descy et al., 2010). Picocyanobacteria are important producers in Lake Tanganyika (Sarvala et al., 2003; Vuorio et al., 2003; Descy et al., 2005). In 2004–2007, photosynthetic picoplankton (mostly picocyanobacteria) comprised 41–99% of the total phytoplankton biomass, with highest values in the south basin in the dry season (Stenuite et al., 2009a). Heterotrophic bacteria are also important producers of biomass (Stenuite et al., 2009b). Heterotrophic nanoflagellates are abundant and diverse, and ciliates with endosymbiotic algae are abundant at times (Pirlot et al., 2005).

Multicellular zooplankton comprises one calanoid species (*Tropodiatomus simplex*), and one medium-sized and one small cyclopoid species (*Mesocyclops*

aequatorialis, *Tropocyclops tenellus*). Peculiarities of Tanganyika are several species of freshwater shrimps (from the genera *Limnocaridina* and *Macrobrachium*), and a medusa, *Limnocyclus tanganyicae* (Coulter, 1991; Kurki et al., 1999).

Advanced developmental stages of *Mesocyclops* are predatory. *Tropodiaptomus* is a herbivore, but it may feed on ciliates, too. Judging from their isotope signatures, the small cyclopoids and shrimps seem to be feeding on algae, particularly cyanobacteria (Sarvala et al., 2003). Big shrimps prey upon zooplankton. The medusae feed on crustacean zooplankton, but they may contain high densities of picocyanobacteria rendering the whole animal visibly pink in color. In adequate light, such medusae are net producers rather than consumers. The medusae have no significant predators, thus being a dead end in the food web.

Fish biology and fisheries

Lake Tanganyika is renowned for its productive pelagic fishery, which is an important source of protein for millions of people in the surrounding area. About 45,000 fishermen are directly engaged in fishing. In the 1990s, the total catches approached $200,000 \text{ t a}^{-1}$ or about $60 \text{ kg ha}^{-1} \text{ a}^{-1}$. Dried fish is sold $>1,000 \text{ km}$ away. The biological basis of the fishery was investigated in 1992–2001 in a comprehensive ecosystem study “Research for the Management of the Fisheries on Lake Tanganyika” (LTR; Mölsä et al., 1999; Mölsä et al., 2002; Sarvala et al., 1999).

There are three main types of fisheries in Lake Tanganyika: industrial purse seines, artisanal lift nets, and various traditional methods, such as scoop nets, gillnets and hook and line (Coulter, 1991). Traditional fishery yields a minor part of the total catch. Most fishing is done at night using light attraction. Major part of the catch derives from the artisanal fishery in which two clupeid species, *Stolothrissa tanganyicae* and *Limnothrissa miodon*, compose about 65% of the total. The most important species in the lift-net fishery is *Stolothrissa* (max. length 12 cm), which spends most of its life in the pelagic area, feeding mainly on copepod zooplankton and also on shrimps. *Limnothrissa* can grow to 17 cm, and feeds on copepods, shrimps, and especially on young *Stolothrissa*.

A typical industrial fishing unit consists of a purse seiner, an auxiliary vessel for the seine, and 3–4 lamp boats. At present, the industrial purse seine fishery targets mainly *Lates stappersii*, the smallest of the four endemic *Lates* (“perch”) species in Tanganyika. It can grow to 50 cm long, but a typical size in the catch is 30–35 cm. Juvenile *L. stappersii* feed on zooplankton, but with increasing size, they gradually switch to feeding on shrimps and fish, especially *Stolothrissa*. The other large *Lates* species, *L. mariae*, *L. microlepis*, and *L. angustifrons*, all potentially growing to 50–100 cm long, became sparse soon after the beginning of purse seining in the 1960s. *L. mariae* and *L. angustifrons* feed largely on benthic fish and partly on shrimps and on the

small clupeids. *L. microlepis* is a specialized predator on *Stolothrissa*.

There is an inverse correlation between the abundance of *Stolothrissa* and *L. stappersii* which is often interpreted as the consequence of predator–prey relations but may mainly reflect the underlying fluctuating limnological environment. Currently, the two species appear spatially segregated in the lake, *S. tanganyicae* dominating in the north while *L. stappersii* is generally abundant in the south where it feeds mostly on shrimps. The abundance of *S. tanganyicae* is positively correlated to plankton biomass, while water transparency, depth of mixed layer, and oxygenated water appear important drivers for the abundance of *L. stappersii* (Plisnier et al., 2009).

The fishing pressure in Lake Tanganyika has steadily increased over the last decades. In the 1990s, the total lake-wide catches of *Stolothrissa* were estimated to be about 25%, and those of *Limnothrissa* 30% of the calculated production, suggesting that the present fishery of the planktivorous clupeids is sustainable. The harvest rates of the *Lates* piscivores, in contrast, were extremely high, and excessive exploitation was likely to occur at least locally in the most intensively fished northern and southern ends of the lake (Sarvala et al., 2002; Mulimbwa, 2006). According to bioenergetic calculations, the food requirements of the planktivorous fish were a reasonable fraction, 25–38%, of the zooplankton production. In contrast, very high predation pressure was indicated on the shrimps and prey fish (Sarvala et al., 2002).

Estimates for primary production vary from 123 to $662 \text{ g C m}^{-2} \text{ a}^{-1}$ (Sarvala et al., 1999; Stenuite et al., 2007). Bacterioplankton production is about 20–25% of phytoplankton production (Sarvala et al., 1999; Stenuite et al., 2009b). Zooplankton biomass (1 g C m^{-2}) and production ($23 \text{ g C m}^{-2} \text{ a}^{-1}$) suggest that the carbon transfer efficiency from phytoplankton to zooplankton is low, in contrast to earlier speculations but in accordance with the apparent importance of the microbial food web. Planktivorous fish biomass (0.4 g C m^{-2}) and production ($1.1 \text{ g C m}^{-2} \text{ a}^{-1}$) likewise indicate a low carbon transfer efficiency from zooplankton into planktivorous fish production (Sarvala et al., 1999; Sarvala et al., 2002). Relatively low transfer efficiencies are not unexpected in a deep tropical lake because of the generally high metabolic losses due to the high temperatures and presumably high costs of predator avoidance. The total fisheries yield in Lake Tanganyika in the mid-1990s was 0.08–0.14% of pelagic primary production, i.e., within the range of typical values in lakes (Sarvala et al., 1999).

Climate change

Recently, concerns have arisen on the possible effects of climate warming on the productivity and fisheries of Tanganyika (O'Reilly et al., 2003; Verburg et al., 2003). Higher temperatures and lower wind stress could result in increased stability of the water column and sharpening of the vertical temperature gradient. The increased

stability would then diminish mixing of hypolimnetic nutrients into the euphotic zone and decrease primary productivity. There is a consensus about recent warming of Lake Tanganyika and several other East African lakes and its consequences to stratification, although the evidence is not unequivocal (Sarvala et al., 2006a; Sarvala et al., 2006b; Verburg et al., 2006). The changing climate is ultimately expected to affect the fisheries yields, but so far the observed variations in fish catches mainly reflect changes in fishing practices and short-term environmental fluctuations, not directional climate change (Sarvala et al., 2006a; Verburg et al., 2006), and even the postulated decrease in primary production is as yet uncertain (Sarvala et al., 2006b).

Historical perspective

Predecessor organizations of Thames Water could be said to date back to circa 1582, when the City Corporation granted permission to Peter Morice, a Dutchman, to lease an arch of London Bridge, where water wheels were constructed, to pump R. Thames water to local housing through a series of wood, and later, lead pipes. This system established the first water supply company in the country – the London Water Works (2005).

By the end of the sixteenth century, the population of London had swelled to approximately 180,000 residents, and London now faced an acute shortage of clean drinking water.

By the turn of the century, Edward Colthurst, a former army captain, devised plans to transfer water by gravity from springs in Hertfordshire to Islington in North London. This was to become the New River (2005).

In 1602, Colthurst received support for the project from the City Corporation, but Queen Elizabeth I was concerned that navigation in the R. Lee may suffer.

A commission was established to investigate these issues, but the Queen died before Colthurst was granted a license to start the work.

In 1604, James 1st granted permission for the work to start provided the New River was no more than 6 ft wide and the work was finished within 7 years.

By 1605, only three miles had been completed, and Colthurst required further funding from the City Corporation. The funding debate dragged on for the next 3 years, when in 1609, the Corporation accepted an offer from Hugh Myddelton to complete the work in four years.

The 40 mile New River was designed to follow the 100 ft contour from Chadwell Spring, in Hertfordshire Herts to the Round Pond at New River Head in Islington.

On Sept 29th, 1613, in the presence of local dignitaries, the New River was opened by the Lord Mayor of London, and the New River Water Company was established.

Fresh water could now be supplied to local residents via a series of fifty eight water mains made from elm tree trunks. One-inch bore lead pipes delivered water to those customers who could afford to pay for the service.

During the eighteenth and nineteenth century, various developments in London's water supply were affected including the construction of an Upper Pond at the New River Head, straightening the course of the New River, and the establishment of eight water companies supplying the Metropolitan area, namely:

Company	Date founded
The New River Company	1619
The Chelsea Waterworks Company	1723
The West Middlesex Waterworks Company	1806
The East London Waterworks Company	1807
The Grand Junction Waterworks Company	1811
The Lambeth Waterworks Company	1785
The Kent Waterworks Company	1809
The Southwark and Vauxhall Waterworks Company	1760

However, concerns about the purity of water were raised after a further outbreak of cholera in 1849 when Dr. John Snow famously determined the causal link between contaminated water and water-related disease, originating from the Broad St. well in Soho. As a consequence, water companies were required to meet new statutory demands, and in 1852, the Metropolis Water Act was established.

The Act determined that all water companies must abstract R. Thames water above Teddington weir (the tidal limit), that all river water must be filtered, and all filtered water must be stored in covered reservoirs.

In 1871, revisions of the Metropolis Water Act determined that water supplies were to be constant, domestic plumbing standards were implemented, and the first "water examiner" was appointed.

In 1904, the Metropolitan Water Board (MWB) was established which took over the responsibilities for water

supply from all the previous water companies. Ten years later, the MWB built its new headquarters on the site of the Round Pond in Islington. It was named New River Head.

Prior to the establishment of the MWB, a number of the previous water companies had erected river water pumping stations in the Lower Thames and Lee Valleys. They were located above the tidal limits of both rivers and designed to pump to a series of small bankside storage reservoirs which had been constructed upstream of the associated water treatment works.

The reservoirs were commonly named after the individual companies, and some are still in operation in the twenty-first century.

For example, at Hampton WTWs, in the Lower Thames Valley, one of the earliest reservoirs built is still in use as a balancing tank at the head of the water treatment works. This "reservoir," built in 1879, was named the Grand Junction reservoir after the original water company. Close by are the redundant Stain Hill reservoirs, constructed in 1898.

Further, to the west, at Kempton Park WTW's, two additional reservoirs were constructed in 1906, namely, the Kempton Park East and West reservoirs.

South of the R. Thames at the Walton on Thames treatment works are four reservoirs which were constructed by the Chelsea Water Company in 1877. Next to them are the four Lambeth Water Company reservoirs, two of which were built in 1874 and the others in 1901 and 1903.

These small reservoirs are now redundant, and following a period of major gravel abstraction, the area will be converted to a wildlife and wetlands nature reserve.

Between 1863 and 1903, in the Lee Valley area, NE London, 11 small storage reservoirs were constructed (details in Table 2, below). They are all in operational use today, either as water supply reservoirs or as sedimentation basins for wash water originating from the Coppermills WTWs.

After 1904, the management of the reservoir complex became the responsibility of the Metropolitan Water Board. The MWB inherited a combined storage volume in the Thames Valley of $196 \times 10^6 \text{ m}^3$.

The 1973 Water Act simplified the way that water and wastewater services were provided in the UK and paved the way for the creation of ten major Water Authorities in 1974.

By the time the Thames Water Authority had replaced the MWB, the ongoing reservoir storage strategy had ensured an additional storage capacity of $150 \times 10^6 \text{ m}^3$, equivalent to approx. 100 days supply to Greater London.

Of the 25 reservoirs originally adopted in 1974, ten strategic reservoirs in the Lower Thames Valley area are those primarily considered in any management decision process.

These ten reservoirs provide a total storage volume of $165.1 \times 10^6 \text{ m}^3$, five of which are of prime importance for water resources in that they contain, individually, more than $19 \times 10^6 \text{ m}^3$ and comprise 82.5% of the total Lower Thames Valley storage volume.

In 1989, a revision of the UK Water Act enabled parts of the UK water industry to be passed to the private sector.

The newly formed Thames Water plc took responsibility for providing water and wastewater services to London and the Thames Valley area in SE England.

Table 1 below lists the major reservoirs located in the Thames and Lee Valleys.

By 2001, Thames Water plc was acquired by the international multi-utility, the RWE Group, with Thames Water becoming RWE's Water Division. Thames Water Utilities Limited (as part of Thames Water plc) is now owned by Kemble Water Holdings Limited (Kemble Water) which acquired Thames Water from RWE in December 2006.

To date, Thames Water, UK, currently supplies clean water services to 8.7 million customers, (2,800 million l/day) from 103 water treatment works through 31,000 km of water mains. Wastewater services are provided to 13.8 million customers via 65,151 km of sewers at 351 sewage treatment works. Where applicable, advanced water treatment processes have been incorporated within the existing treatment works. These additional processes include the use of ozone and granular activated carbon treatment to assure compliance with the exacting pesticide regulations and phosphoric acid dosing facilities to assure lead compliance at customer's taps.

13,100 km², comprising a varied mixture of urban and rural development. Each river system receives runoff from lowland agricultural land and a significant number of sewage treatment works. The characteristics of the river sources are typical for those of a lowland river in a temperate zone (Toms, 1987).

Previous management strategies suggested that the R. Lee and groundwater sources were at their maximum for exploitation and any shortfalls would be met by increased abstraction from the Thames Valley basin.

However, over the past decade, with the impact of climate change, i.e., longer drier summers and shorter wetter winters, has resulted, on occasions, in a negative supply/demand balance for London. As a consequence, a number of strategies have been developed to stay ahead of the rising demand for water. These include the resurrection of some redundant aquifer sources, exploitation of new aquifer sources, further development of the aquifer storage and retrieval system, by 2007, the operation of a desalination plant located on the north bank of the Thames estuary at Beckton, and possibly, by 2020, a new bankside storage/river-regulating reservoir located in the Upper Thames area of Oxfordshire.

The role of bankside storage reservoirs

Introduction

Approximately 70% of London's water supply is sourced from the River Thames; 15% sourced from the River Lee and the remainder from boreholes in the surrounding chalk aquifers. The total catchment area is approximately

Characteristics of the surface water sources

All the exploited river sources can be described as eutrophic, with nutrient concentrations of approximately 0.5–1.5 mg PO₄-P l⁻¹, 5–15 mg NO₃-N l⁻¹, and up to 20 mg SiO₂ l⁻¹.

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Table 1 Major reservoirs located in the Thames and Lee Valleys

Thames Valley reservoirs	Date completed	Depth, m	Area, Ha	Volume, 10 ⁶ m ³	Mixing method
Staines, north	1902	8.0	72.0	7.2	Air domes

William Girling	1951	12.5	135	15.8	Jets/sparge pipe

During periods of mod-high flow, the river can also contain high organic carbon and silt loadings, ranging between 0.5 and 6.0 g C·m³, and turbidity values ranging from 10 to 100 NTU.

The river systems can also support a range of microbiological and algal species at varying concentrations dependant on the rainfall values, flow conditions, and season impacts. In spring and summer when flows are lower, the river can be highly productive with phytoplankton biomasses values in excess of 200 mg-Chla/m³ recorded, the dominant algal species generally the centric diatom, *Stephanodiscus hantzschii*.

Reservoir classification, morphology, and management

As illustrated in Table 1, the principle Thames Valley and Lee Valley storage reservoirs were constructed between the period 1951–1974, resulting in a doubling of the total storage capacity from approx. 100–200 Mm³ (Steel, 1975).

The reservoirs can be classified as eutrophic bankside storage reservoirs or pump-storage embanked reservoirs, as opposed to a dammed valley type reservoirs.

Good examples of this mode of construction are the Wraysbury reservoir near Staines, Middx, and the Queen Elizabeth II reservoir, West Molesey, Surrey.

Overlain by drift sediments and river gravel, the underlying geological formation of the Thames Valley consists of a layer of largely impermeable clay. The clay layer forms the base of the reservoir. An impermeable clay core is supported both inside and out by an earthwork embankment constructed from the gravel and ballast mined from the reservoir basin (Bayley, 1998).

The internal embankment is lined with concrete to prevent wave erosion with a wave wall to prevent overtopping. The external embankment is grassed over, and maintained by sheep grazing. The puddled clay internal core is keyed into the underlying clay layer to form a watertight seal. As the structure is built up from ground level, all the water entering such reservoirs has to be pumped from the river source, in this case the R. Thames or R. Lee.

In some of the older reservoirs, significant quantities of gravel were left on the reservoir floors. In selected reservoirs, the alluvial gravels are being dredged out and processed for use in the building industry or for highway construction.

All Thames Water reservoirs have similar, simple morphologies, with steep internal sides lined with concrete, and a relatively uniform depth. They are operated with known quantities of throughput water with the aspiration to maintain a uniform mixed depth when in supply. Retention times can range from 10 to 100 days.

The current reservoir management strategy, as per the best operating practice document, does not regard each reservoir in isolation. Water operations now recognized that the reservoir complex is an integral part of the overall water supply chain. The system not only enables provision

of a reliable water source during drought periods but also provides an important first treatment stage in the water supply process.

In addition, the reservoirs also act as a safeguard when point source pollution events occur in the rivers. Thames Water and the Environment Agency have linkages with their continuous river water quality monitoring stations via a series of control rooms. In the event of a gross pollution, one management option is the closure of intakes for an extended period thereby safeguarding supplies of water to London.

Of interest, it was Frankland who, in 1894, identified that storage of polluted river water for periods of 2–3 weeks can result in a significant reduction in concentration of intestinal bacteria with virtual elimination of pathogenic species and reduction in turbidity. The current operational retention periods account for this natural reduction and are contributory to ensuring that the silt and microbiological loadings onto the receiving water treatment works are minimized (Ridley and Steel, 1975).

During the early period of reservoir construction, designers tended to ignore the ecological importance of the depth volume ratio of the water mass. Hence, the early reservoirs were constructed as shallow impoundments (<10 m depth) with a large surface area as opposed to a “modern” reservoir with depths up to 25 m and requiring less land area (<200 ha).

In temperate climates, the water column of a shallow basin is likely to be well mixed for most of the year, whereas deeper basins have a propensity to thermally stratify during the summer months. Therefore, the depth of the water relative to the surface area will have a significant impact on the overall environmental status of an individual reservoir and influence biological productivity.

During the period 1926–1950, reservoir source selection and management options were limited. The available reservoirs often supported large crops of diatoms and blue-green algae, which, on occasion, severely constrained the associated water treatment processes and often limited supply (Steel, 1975).

Various attempts at algal control in Queen Mary reservoir were undertaken including mass dosing of copper sulfate (up to 1 mg/l Cu), low-level continuous dosing of between 0.1 and 0.3 mg/l Cu, or closure and switching to an alternative source.

However, the alternative source generally the KG V1 reservoir was regularly subject to a stable thermal stratification phenomenon.

Thermal stratification may occur on any large, deep lake or reservoir in temperate climates. Generally, the surface area has to exceed 1 km² and with depth exceeding 10 m. Stratification on smaller, shallower water bodies tends to be localized and transient.

There are two periods in the year when thermal stratification can occur: winter and spring. The main thermal stratification impact is likely during spring, while an inverse stratification may occur in winter if ambient

temperatures are low for an extended period, then the reservoirs can ice over.

Reservoirs that stratify once a year are termed "monomictic," while those that regularly stratify twice a year are termed "dimictic."

Thermal stratification of a water body results because water has a maximum density at 4 °C and that water has a high specific heat (approximately $4.2 \text{ J.g}^{-1}.\text{°C}^{-1}$). During spring and early summer, the upper layers of the water column are warmed and, as a result, become less dense. Gradually, a distinct layered structure develops in the water column with a warm top layer, a cold denser deep layer with a dividing region between these layers called the thermocline, characterized by a temperature change of 1.0 or more degrees Celsius per meter depth.

The warm upper layer is known as the epilimnion and the cold dense layer, the hypolimnion. The thermocline acts as an almost frictionless layer and also forms as an effective barrier to rapid diffusion of chemical species. In deep basins, this thermal stratification is stable due to the low center of gravity of the water column.

Algal growth under these conditions can only take place where there is sufficient light for photosynthesis. The algal populations may grow until limited by the available light (self shading) or other ecological factors such as grazing by zooplankton and the impact of high fish biomasses.

As the available light energy reduces exponentially with depth, then the euphotic depth (m) is defined as the depth at which useful light or "photosynthetic active radiation" (PhAR) can penetrate.

The rate at which light is adsorbed with respect to depth is known as the extinction coefficient (m^{-1}).

Unmixed, stratified basins tend to have small extinction coefficients with large euphotic depths. Hence, in a stratified system, algal growth will be confined to the epilimnion dependant on the epilimnion depth and the euphotic depth, and because any algal growth is not limited by nutrient availability, significant algal populations may develop. Hence, the epilimnion water will become difficult and expensive to treat.

In addition, any dead and decaying algae will sediment through the depths and enter the hypolimnion. As there is insufficient light at these depths to sustain further algal growth, they intern will die. At first, decomposition of the algae can take place relatively rapidly while dissolved oxygen levels remain high, but eventually, the decomposition processes will remove all the oxygen from the hypolimnion, exacerbated by the thermocline acting as an effective barrier to oxygen diffusion from the epilimnion.

At this stage, bacterial species can utilize dissolved nitrate and reduce any nitrate to ammonia. The anaerobic processes will then continue to utilize any insoluble manganese (II) and iron (II) compounds present with eventual reduction of sulfates to either sulfide or elemental sulfur.

At this stage, the hypolimnion water is likely to be black in color and smell of rotten eggs. If light can

penetrate through to the hypolimnion, the water may have a purplish-pink color (due to particular species of bacteria) though still having a foul, rotten egg odor.

Thus, a stratified reservoir can contain water that is virtually untreatable due to low dissolved oxygen concentrations, high ammonia and/or sulfide compounds, i.e., the hypolimnion, or difficult and expensive to treat due to high algal biomass values, i.e., the epilimnion.

Under these conditions and if a seiche is present, i.e., an internal oscillation of the thermocline, then a reservoir outlet with specific depth drawoffs may experience periodic epilimnetic and hypolimnetic water during the course of a few hours or days. Oscillations of 4 m amplitude have been recorded within the Thames Water, KGV1 reservoir.

Studies by White et al. (1955) suggested that thermal stratification could be controlled by internal mixing using submerged jets. Their studies were fundamental in the design of subsequent reservoirs and were incorporated within the Queen Elizabeth II reservoir built in 1962 (White et al., 1955).

Further developments in hydrobiology research have contributed to a greater understanding of the physico-chemical and biological interactions that occur within the storage reservoirs. It is now recognized that mixing and manipulation of deep pumped storage reservoirs can have a significant impact on the ecology of the basins. All subsequent Thames Water storage reservoirs have had jet mixing systems incorporated within their design.

The design of the inlet and outlet structures has also progressed from simple shoreline inlets and outlets to modern inlet piers with a selection of low-velocity inlets and high-velocity angled jets and centrally located wet tower outlets with multiple drawoff levels.

Note that inlet jetted systems can only operate when abstracting from the river, so if abstraction is curtailed, internal recirculation pumps are available to maintain a mixed basin.

When operationally feasible, some of the older reservoirs (constructed pre-1962) have had internal air mixing systems installed, using either a series of air diffusers or sparge pipe systems.

Algal biomass manipulation

In addition to securing stored water resources, another primary objective of reservoir management is to supply stored water to the receiving works with minimal presence of biological particles, i.e., algae.

As previously stated, the inbuilt mixing mechanisms are designed primarily to minimize the impact of thermal stratification. However, an additional component is the successful manipulation of the phytoplankton biomass with important benefits for water treatment works process control, cost efficiencies, and security of supply.

For each reservoir, there is a theoretical minimum retention period, when all the river-derived algae should have died off and limited lacustrine algae will develop.

Minimum retention periods of 5–10 days are often quoted, but as the reservoirs have been designed to

provide between 30 and 100 days storage, these values are impractical to achieve.

Under the current mode of operation, the lacustrine algae have the potential to achieve their theoretical growth maxima, hence the development of low-cost engineering solutions (jet mixing/aeration mixing) to improve circulation in deep basins, minimize the impact of thermal stratification, and concurrently influence phytoplankton productivity.

Modern computational fluid dynamic (CFD) techniques can now be applied to understand the flow characteristics of each reservoir under varying inlet and outlet configurations.

As previously stated, in the Thames Valley reservoirs, nutrient concentrations are high, and the water is classified as eutrophic. Simplistically, this means that algal growth is unrestricted by available nutrients.

In reality, the algal taxa have different requirements for the major nutrient elements and micronutrients. All algae require phosphorus in a suitable form, and most taxa require an inorganic nitrogen source.

The majority of Cyanobacteria ("blue-green algae") are able to fix atmospheric nitrogen. Diatoms typically require dissolved silicates to form their frustules. In the UK, micronutrients (e.g., boron, molybdenum) are not usually limiting.

Within the Thames Valley reservoirs, the nutrient concentrations are over two orders of magnitude greater than that required for maximal algal growth.

In addition, recognition that certain species of algae may form a potential threat to human health in the form of toxins will influence the management of the reservoir complex.

In marine environments, the most notable events often involve the paralytic poisoning of shellfish from marine dinoflagellates (Bayley, 1998).

Within freshwater ecosystems, the most recent concerns have involved some genera of Cyanobacteria. The toxins produced have been classified into three main groups: the hepatotoxins, the neurotoxins, and polysaccharide complexes.

Recent work has concentrated on the most common hepatotoxin, microcystin-LR and, to a much lesser extent, the neurotoxin anatoxin-a. The risk to health is believed to be mainly from ingestion of the cells themselves, and a relatively large dose is required to have an impact on human health.

Filtration and other treatments (use of ozone and carbon adsorption) are effective at removal of these cells and toxins. The greatest risk is when people consume contaminated water with little or no treatment or participating in water sport activities where decaying blue-green algae scum is present.

Thames Water and the UK Environment Agency have a requirement to be aware of the potential of the reservoirs to support toxic blooms of Cyanobacteria.

Advice and guidance is delivered to all operatives and those who take part in water-based recreational activities.

Large populations of algae are also undesirable in terms of both aesthetic parameters and potable water treatment costs. Under certain conditions, undesirable taste and odors can be produced by many species of algae. The most common chemical compounds responsible for bad taste and odor are 2-methylisoborneol (MIB) and geosmin. One algal species, *Synura petersenii*, produces two compounds causing tastes of "cucumber" and "fish" at very low cell densities.

In terms of the water supply production, the most problematic issue associated with algae is the potential to increase treatment costs and a possible reduction in work output.

Compliance with the UK Water Supply Regulations 2000 and the TW Best Operational Practice documents requires that water be treated to remove algae and other contaminants.

Such treatments are very effective but can become overwhelmed by large communities of algae.

While there is no direct risk to health, occasionally, the volumetric output of treatment works can be severely constrained, and treatment costs increased. Thames Water has recognized these issues and routinely monitors the water quality status at all stages of the treatment process. The data set is used to produce short-term forecasts of expected changes in water quality and for use in new works or reservoir design programs.

Within a "managed" basin, i.e., one where a variety of reservoir management tools are available to influence the flow characteristics of the reservoir and low-velocity inlets, combinations of varying angled jet inlets (0°, 22.5°, and 45° to the horizontal) and internal recirculation pumps have been incorporated within the designs.

The current mode of operation determines that during the autumn/winter period, the river water is abstracted through the low-velocity inlets. Prevailing climatic conditions ensure that the temperature profile is homogeneous, hence no requirement to "jet" mix. Operation of these units also promotes sedimentation of the river derived inorganic silt. Accumulation rates of allochthonous and autochthonous material have been estimated between 5 and 10 mm per year, depending whether the reservoir is operated as a continuous throughput basin or a standing reserve.

The problems associated with thermal stratification can mean that the capacity of a reservoir is not always available for use when required. Up to the middle of this century, reservoirs in the London area were built fairly shallow, and thermal stratification was uncommon. The demand for more water resources, however, meant that larger, deeper reservoirs were required. As a result, trials of various artificial mixing devices were initiated.

They included:

1. Floating recirculation pumps delivering hypolimnion water to the epilimnion
2. Jet mixing through narrow inlet jets located on the reservoir floor with entrainment of the water mass in the jet plume

3. Diffused air mixing where compressed air is blown into the reservoir through a series of diffuser heads

Of the various trials undertaken, jet mixing was selected as the standard design for Thames Water's de-stratification strategy. These devices were added to the newer, deeper basins during construction (Ridley et al., 1966).

Further studies have indicated that jet angles between 0° and 15° would be preferable.

Also note that jet mixing can increase pumping costs by 2–3%.

The jets themselves do not mix the reservoir directly as the velocities and energy involved will be insufficient. River water temperatures are generally greater than those in the reservoir, and this temperature differential assists jet-induced mixing. The jet of water entering the water body at high velocity entrains a relatively large volume of reservoir water. The magnitude of the water masses is of such stature so as to be influenced by the Coriolis effect of the earth's rotation and when prevailing wind direction is taken into account, full-depth mixing of the large basins has been achieved within 48–72 h at little extra cost. At the outlet, the drawoff levels can be altered to take advantage of differences of quality through the depths.

If the jets are started when a temperature differential is first recorded (generally 2°C , top–bottom), then thermal stratification can be controlled. The jets are normally turned off when temperatures start to fall at the end of the summer months.

Figure 1 illustrates one-half of the inlet jet configuration of Wraysbury reservoir, in operation since 1971.

Diffused air mixing for algal control

During the 1970s, it was decided to attempt to de-stratify some of the older reservoirs (depth range of 8–16 m) using diffused air mixing. Retrofitting jetted inlets was deemed uneconomic and involved draining the reservoirs with associated major civil engineering works. A number of devices were investigated with diffused air bubble plume mixing selected as the practical and cost-effective method. The procedure is relatively simple and described in detail by Goosens (1979).

Similar systems have been successfully deployed in the Netherlands within the Biesboch water storage scheme (Oskham, 1983).

To date, diffused air mixing through point source diffusers has been installed within the KGV1 and Staines north and south reservoirs in the Thames Valley and a perforated pipe system in the Lockwood and William Girling reservoirs in the Lee Valley area.

Mixing efficiency is determined by the degree of stratification, epilimnion thickness, injection depth, and the number of injection points.

For effective operation, a series of diffuser heads ($3 \times$ sets of 6) were placed some 2 m below the floor of the reservoir and supplied with up to $0.3 \text{ m}^3/\text{s}$ with oil-free air, which will lift approximately $50 \text{ m}^3/\text{s}$ of water to the surface. Figure 2 illustrates one set of diffuser heads within

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Figure 1 Wraysbury reservoir inlet jets showing different angles from the horizontal.

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Figure 2 Air mixing diffuser blocks located within KGV1 reservoir, Thames Valley.

KGV1 reservoir installed in the 1980s, in dry conditions coinciding when the reservoir was drained for operational purposes.

The diffusers used include sets of ceramic domes, more usually used for sewage works activated sludge plants and purpose built foam rubber blocks. More recently, porous flexible hose has been used. Air mixing does not significantly aerate the water directly, but each bubble acts as a lift mechanism thus transferring water from the lower layers to the surface. A bubble plume with entrained water rises to the surface where mixing takes place below and

within a visible "boil." Water to air movement ratios have been estimated to be in the order 1:240.

The prolonged drought of 2005–2006 which affected Southeast England significantly reduced river flows and available volumes for abstraction.

By early 2006, it was apparent that if the predicted hot and dry period continued into the summer, then reduce treatable reservoir volumes would be limited by reduced or no abstraction thus negating any inlet jet mixing. The impact would be the potential for stable thermal stratification, a resultant deterioration in water quality with

excessive algal growths, etc. As a result, an internal emergency drought scheme was implemented to preserve the treatable volumes held within four major reservoirs in the Thames and Lee Valleys to assure the security of drinking water supply to London.

The design an air mixing system suitable for large open reservoirs was based on the paper by L Goosens (Delft University Press) "Reservoir Destratification with Bubble Columns" which describes a design for an unconfined diffused air mixing system.

A number of factors were important:

- For each level stratification and water depth, there is an optimum air flow rate.
- Air needs to be introduced at depth (i.e., the lowest points on the reservoir floor). This factor indicated that an air mixing system would be more effective in deeper reservoirs.
- The air needs to be in the form of small bubbles and released at a calculated number of diffusing points in the reservoir (three to four per reservoir).
- The rising vertical pattern of the plume would raise the bottom water to the top of the reservoir and induce mixing with the warmer layers.
- Each air system needed to be arranged with spare capacity and adjustment to enable the flow rate to be varied to accommodate seasonal reservoir temperature differences.
- The number of diffusion points and air flow rates had to be evaluated for each individual reservoir.
- Temperature gradient top to bottom and required homogenizing time.
- Ambient air temperature and humidity.

The reservoirs chosen for installation of a new air mixing system were the larger and deeper reservoirs, namely Queen Mother, Wraysbury, Queen Elisabeth II, and William Girling. The size and depth of these reservoirs are as follows:

	Max depth (m)	Max usable volume (megaliters)
Queen Mother	25.9	38,000
Wraysbury	21.39	33,874
Queen Elisabeth II	17.83	19,623
William Girling	12.5	16,511

The concept of air diffusion is common in the aeration lanes of a sewage treatment works but not at considerable depth (>20 m) at the bottom of a reservoir. The only type of known diffuser considered suitable for the application to create the fine bubbles required for the air mixing system was the *Sanitaire* Fine Bubble Membrane Tube (see Figure 3).

This type of diffuser was designed for use at relatively shallow depths (down to 5 m), and it was suggested that there may be a potential weakness in the tube construction if exposed to the higher pressures at greater depth. Factory checks by the manufacturer in a pressure chamber confirmed the suitability of the *Sanitaire* units at the higher pressures. For each diffusion point in the reservoir, a grid of 32 *Sanitaire* diffuser tubes was provided to give the required air flow.

The air requirements for mixing of the reservoirs were calculated and specified as follows:

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Figure 3 *Sanitaire* diffuser platform (half section shown).

Queen Mother reservoir – 0.191 m³/s free air delivered (FAD) at a nominal 35.6 m H₂O to four off-delivery points

Wraysbury reservoir – 0.197 m³/s FAD at a nominal 36.1 m H₂O to a four-point delivery system

Queen Elizabeth II reservoir – 0.165 m³/s FAD at a nominal 36.4 m H₂O to a three-point delivery system

William Girling – 0.151 m³/sec FAD at a nominal 36.4 m H₂O to a three-point delivery system

Each air system was arranged with spare capacity and adjustment facilities to enable the flow rate to be varied to accommodate seasonal reservoir temperature differences.

Air was provided using shore-based compressor systems installed within containers together with long (1.0–1.3 km) air delivery lines routed up and over the reservoir embankment and long submerged lengths on the reservoir bed to each diffuser platform.

The compressors operate at a higher pressure than the nominal calculated delivery pressure to the reservoir in order to provide a differential across a regulating valve. The flow capacity of the compressor was also approximately 20% oversized to allow for seasonal adjustment of air flow rates (Figure 4).

Installation method

The wet side installation involved the development novel techniques for floating out and sinking long pipelines and aeration platforms in a controlled fashion to precise locations on the reservoir floor. A marine installation contractor (Ocean Team 2000) was appointed for installation of wet side elements, and Costain acted as main contractor for the whole project. Installation methods were developed in liaison with the contractor. Important aspects are as follows:

- Bathymetric surveys were carried out over the whole reservoir area to ascertain the bottom topography and

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Figure 4 Typical diffuser layout in reservoir.

determine the most suitable low points on the reservoir floor (for diffuser location) and to ascertain the depth of silt.

- The proposed positions for the diffuser platforms and alignments for the submerged pipelines were selected to ensure that the area of the reservoir bed for the diffuser platform is level and that there are no significant underwater valleys, slopes, high points, etc., along the pipeline route that might result in excessive pipeline strain.
- The diffuser platforms are made in two sections to allow road transportation. They are fabricated using stainless steel rolled rectangular hollow sections and shall be structurally robust as separate sections and conjoined. The arrangement allows removal and replacement of individual diffusers.
- The design of the diffuser platform allows for future recovery to maintain/replace diffusers and the like. A non-return valve and release coupling have been incorporated to prevent water entering the air line when detached from the platform.
- The diffuser platform has negative buoyancy, but the polythene air pipeline required weighting to achieve submergence in the reservoir. This was achieved using a weighting cable clipped to the pipeline along its length.
- A team of divers was used for the installation together with a fully equipped diver support boat (RIB).
- The diffuser platform positions were inspected by divers to check for suitability.
- Both platform and pipeline were supported initially by buoys and the assembly drawn out into the reservoir using the RIB until above the diffuser position and air line route.
- Working from the shore, the buoys were cut from the air line progressively and the settlement of the air line onto the reservoir floor checked using divers. This was continued over 1 km or so length of pipeline to the diffuser platform.
- A line with a string of buoys was used to stabilize the descent of the diffuser platform. Buoys cut from the platform caused the latter to sink, but this submerged additional buoys on the string which provided a controlled rate of descent. When recovering the platform in the future, it is envisaged parachute bags will be required to give a controlled rate of ascent. Buoys would expand as depth reduces caused ascent to accelerate.
- The positioning of the platform on the reservoir floor was checked by divers.
- The installed positions of the diffuser platform and submerged pipeline positions were recorded to enable future recovery/maintenance. A post-installation bathymetric survey for each reservoir was undertaken to record the diffuser platform and air line positions.

The installation as a whole over four reservoirs comprised approximately 15 km of MDPE pipeline and

3–4 aeration platforms per reservoir. Four hundred and forty-eight diffuser heads were shipped from Spain, three compressors were shipped from Germany, over 15 km of pipe work was installed both under water and within the reservoir earth wall, and 225 kW of power was secured and installed across the sites during the delivery of this project.

The first of the four reservoir mixing systems was completed and commissioned just after a period of hot weather in early June 2006. This provided an opportunity to test and prove the effectiveness of the system and whether the design brief was appropriate.

The project also incorporated the installation of a depth profile samplers, one of which was located at a limnological tower within the Queen Mother reservoir. These units enable the collection and recording of real time of vertical water quality criteria every meter depth. The quality sonde is able to record temperature, dissolved oxygen, conductivity, pH, turbidity, chlorophyll a, and phycocyanin.

Figure 5 illustrates the resultant temperature profiles recorded and demonstrates the impact of the mixing

system as each successive aeration dome unit was “switched on.”

Prior to June 7, 2006, before the mixing system was started, the reservoir was thermally stratified with the thermocline developing at approx. 10 m. The progressive de-stratification impact to isothermal conditions as each diffuser dome was operated is ably demonstrated, and by June 24, the reservoir was fully mixed.

Pending operational demands, some reservoirs will not be required for supply purposes and revert to a standing reserve, i.e., no input or output. Under this circumstance, if mixing is not maintained and pending on the season, thermal stratification may occur. Recirculating pumps have been installed specifically for the purpose and operated to minimize stratification impacts. Such recirculation has an associated cost but is outweighed by the advantages of maintaining the resource capability and treatability.

The flexible reservoir management philosophy adopted is a balance between the requirements of water supply, seasonal loadings, operational catchment status, operational costs, and resources.

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Figure 5 Queen Mother reservoir, 2006 – temperature isotherms profiles.

The impact of artificial mixing on phytoplankton growth

As previously suggested, a significant benefit of artificially mixing deep reservoirs is a significant reduction in algal population growth.

Within an efficiently mixed reservoir, the mixed depth will equate to the total depth of the reservoir and provide the correct mixing regime and is maintained with the mixed depth several times the euphotic depth; then, any phytoplankton populations will spend a greater proportion of their time in low-light conditions. The carbon loss from respiration is then greater or equal to the carbon gain from photosynthesis with a net effect of an overall reduction in growth rate and lower algal populations.

In addition, light energy reduces exponentially with increasing linear depth (note that not all light is useful to algae – the useful light is described as photosynthetic available radiation or PhAR).

The rate at which light is absorbed with respect to depth is called the extinction coefficient (a function of the Beer–Lambert law).

If PhAR is able to extend to the floor of the reservoir, then algal growth will not be limited until the algae “self-shade,” i.e., until the algal cells near the surface shade-out the ones below, i.e., the algae then are light limited.

In deep reservoirs where PhAR is absorbed near the surface, algal growth will be concentrated in the upper layers. This zone is called the euphotic zone, and the depth at which any further algal growth is inhibited is the extinction depth.

Note that all phytoplankton require a minimum quantity of light to survive, grow, and reproduce.

In deeper reservoirs, algal growth is restricted to a zone where there is sufficient light; this zone forms a relatively shallow layer near the water surface, between 8 and 10 m.

The use of artificial mixing devices can prevent any thermal stratification impact, and as a result, particles, including algae, will be mixed throughout the water column, so in deep reservoirs, the algae will be removed from the euphotic zone as they are circulated into the lower depths, hence limiting the algal growth as the quantity of PhAR will be effectively reduced. The effect can be compared to reducing the photoperiod, i.e., day length. Therefore, deeper reservoirs will have a larger extinction coefficient and a greater potential to reduce algal growth.

In summary

Algal growth and algal population density are reduced if the reservoir (mixed) depth is several times the euphotic depth. The effective reduction in available light energy delays the start, magnitude, and duration of any algal populations.

Figure 6 below illustrates the variation in algal growth within three Thames Valley reservoirs.

1. Queen Mary reservoir – shallow (11 m) and is not artificially mixed – algal growth is high with considerable chlorophyll *a* values.
2. Queen Elisabeth II and Wraysbury reservoirs are both artificially mixed using inlet jets. The depths for these two reservoirs are 17.2 and 21.5 m, respectively.

In general, algal control is good with Wraysbury reservoir having the lowest chlorophyll values.

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Figure 6 Variation in algal growth within three London reservoirs, 1986–1994.

Other aspects of reservoir management

The structural characteristics and operation in the storage reservoirs make them ideal candidates for ecological modeling. Steel (1972) developed the original Talling model (1957a) to establish that for diatoms in a mixed deep basin:

- Algal growths start later
- The growth rate is constrained
- The maximum biomass is light energy limited and not nutrient limited

From Steel and Duncan (1999), it is recognized that the development and application of ecological and environmental knowledge for algal control within the Thames Water reservoirs is a complex and iterative process.

In addition to the use of full-depth mixing, which Duncan (1990) described as a “bio-manipulation technique,” the use of ecological manipulations or other bio-manipulation techniques could also offer real benefits for reservoir management.

Other biomanipulation techniques include

Continuation of river abstraction during the winter period to provide adequate food sources to “over-winter” the population of grazing zooplankton. In simple terms, zooplankton populations will consume any developing algae, the larger animals having a greater surface area of filtering combs which exert a greater grazing pressure on the developing algal populations.

However, the zooplankton are also grazed by any resident fish populations, hence another manipulation that could be applied is to reduce the number of certain fish species.

If the fish species that predate on zooplankton are removed, then the potential to reduce algae by zooplankton grazing will be increased (Renton et al., 1995).

In recent years, there has also been speculation of the effects of introducing top predator fish to eat the fish that predate on the zooplankton.

All these techniques contribute to the ongoing debate on how best to control the development of algal populations within storage reservoirs.

Figure 7 below illustrates the quantification of top-down effects in the trophic cascade hypothesis in three deep mixed Thames Valley reservoirs, data from the Czech Rimov reservoir is included.

Other speculative methods of algal control have involved the introduction of algal parasites; Chytrids have also been considered but are impractical at present.

The introduction of chemicals to kill algae has been previously mentioned.

Historically, copper sulfate used to be dosed in London's reservoirs but with mixed success. The main problems are associated with dosing the chemical and the subsequent impact on non-target species. Dead and decaying algae can introduce taste and odor problems to the water supply process, and floating, decomposing Cyanobacteria scums can be unpleasant to water body users and people living nearby. Dosing copper sulfate into acidic waters with little alkalinity may result in water quality problems in terms of regulatory failures. Copper salts may exacerbate later algal growth by killing zooplankton.

Chlorine has been used in some parts of the world. One of the main problems with the use of chlorine is that it tends to kill most of the zooplankton as well as the algae and the formation of undesirable by-products such as trihalomethanes (THMs). There are strict regulatory controls

Thames Water: Development of London's Potable Water Supply and the Role of Bankside Storage Reservoirs, Figure 7
Top-down effects in the trophic cascade hypothesis, from Steel and Duncan (1999).

on THMs and other by-products in most countries (WHO, EC, USEPA, etc.).

Where the water is eutrophic, it may be possible to reduce the available phosphorus concentration. In some locations within the UK, (not Thames Water) this has been applied with mixed success and is likely to succeed only in the short term. Generally, attempts at controlling phosphorus loadings have been by dosing with iron (III) salts. In alkaline water, considerable quantities of these salts are required to precipitate the phosphorus compounds. In acidic waters, the *pH* may exclude the use of iron salts. It is usually more economic to install mixing devices although in some basins, this may be impractical (shallow reservoirs with gently sloping sides), and the use of iron salts may be a consideration.

Maximizing the retention time in reservoirs is important in reducing the density of pathogenic microorganisms.

In the Thames Valley reservoirs, provided an appropriate retention time is achieved, a reduction of more than 99% of the fecal indicator species *Escherichia coli* has been recorded.

Recent desktop studies into the use of alternative techniques to control and monitor algae in deep storage reservoirs have included:

1. Alternative mixing devices
2. Artificial shading using floating reed beds
3. The application of barley straw
4. Ultrasound treatment
5. In-reservoir filtration
6. Floating pods with instrumentation recording real time data for early warning of algal bloom periods

Whatever techniques are used to control algal growth within the reservoir management complex, the inherited bankside storage reservoirs will remain an integral part of the source to tap treatment process philosophy adopted by Thames Water, UK.

THERMAL BAR

Arkady Terzhevik

Laboratory of Hydrophysics, Northern Water Problems Institute, Karelian Scientific Centre, Russian Academy Sciences, Petrozavodsk, Russia

Synonyms

Frontal zone

Definition

Cold zone – A cold-water lake area beyond the thermal bar involved in a three-dimensional convection.

Thermal bar – A frontal interface characterized by a strong mixing of waters at and near the temperature of maximal density in large deep temperate lakes during spring warming.

Warm zone – A stably stratified shallow warm-water lake area between a shore and the thermal bar.

Introduction

The thermal bar (hereinafter TB) is one of the most intriguing phenomena in physical limnology. In late spring, when lake warming starts, the total heat flux on the water surface varies in horizontal slightly. As a result, shallow near-shore areas are heated faster than deeper parts of a lake. As we know, the maximal freshwater density (T_{MD}) corresponds to the water temperature $T_{MD} = 3.98^{\circ}\text{C}$, with the parabolic density decrease on both sides from T_m that leads to the development of stable stratification in shallow areas (a warm zone) and a hydrostatically unstable situation in deep parts

of a lake (a cold zone). In the vicinity of the isotherm $T = T_{MD}$, one may expect formation of the double-cell convection with a strong descending current between the cells, which acts as a barrier and inhibits transport of waters from one zone to another and their mixing. Thus, most of dissolved substances including pollutants that come with waters of inflows are trapped in the warm zone. This relatively narrow area can be considered as a frontal interface and is called the thermal bar. As warming proceeds, TB propagates offshore until the deep-water temperature reaches 4°C . In such large and deep lakes like the Great Lakes in North America and Europe, the TB existence may last about 1 month. Hypothetically, the same phenomenon may occur in autumn due to preferential cooling of shallow near-shore regions. The effect of the autumnal TB is likely much lesser because of strong wind-induced dynamics and smaller temperature gradients typical for this season.

The discovery of TB belongs to the Swiss scientist François-Alphonse Forel, founder of limnology, who had qualitatively described its physical nature observing behavior of water temperature in Lac Lemman and termed the phenomenon “barre thermique” (thermal bar) (Forel, 1880). It took more than 50 years before the first detailed observational data became available. The Russian (Soviet) scientist Aleksei Tikhomirov has initiated the study of the thermal regime of Lake Ladoga – the largest European lake – including thorough research of TB; first in its northern Yakimvsky Bay (Tikhomirov, 1959) and then in the lake itself (Tikhomirov, 1963, 1968, 1982). Having used the basic ideas on formation of oceanic fronts, he had proposed a qualitative description of the double-cell circulation (Figure 1). His hypothesis was supported by observations of foam, oil, and small floating objects forming a band at the surface of thermal bar zone. The next detailed field TB studies have been performed by G.K. Rodgers (1965, 1966, 1968, 1971) in Lake Ontario. His findings confirmed the main results of Tikhomirov’s research. Based on heat content change estimates, both Tikhomirov and Rodgers suggested existence of heat advection directed from the warm zone toward TB. Rodgers also

suggested that a circulation pattern formulated by Tikhomirov is secondary compared to geostrophic currents in the warm zone, which are at least ten times stronger.

The thermal bar phenomenology

As it comes from the scaling analysis, the main parameters governing the TB propagation rate (TBPR) are the total heat flux on the water surface Q_s , bottom inclination, and the initial water temperature (heat content) of a lake T_0 . Indeed, in spring within a wedge-shaped basin with bottom inclination tangent μ the temperature change $(T - T_0)$ of a single water column with depth D in certain time t depends on the heat flux applied to a water column. Assuming for simplicity that Q_s and μ are constant in time and space, respectively, and heat advection is negligible, one can write, in a very simplified form,

$$\frac{T - T_0}{t} = \frac{Q}{D} = \frac{Q}{l\mu} \quad (1)$$

where $Q = Q_s/(\rho c_p)$ is the kinematic heat flux; ρ water density; c_p specific heat of water at constant pressure; and l is a horizontal distance from a shore to the isotherm $T(l) = T$. Substituting $T = T_{MD}$, the propagation rate l/t can be defined from (1) as follows:

$$\frac{l}{t} = \frac{Q}{(T_{MD} - T_0)\mu} \quad (2)$$

Thus, the higher Q and T_0 and the smaller μ , the faster TB propagates. The expression (2) was formulated by Elliott and Elliot (1970) in their laboratory study of the TB behavior in the wedge-shaped laboratory tank. According to their estimates based on results of experiments, TBPR was about $3 \cdot 10^{-4} \text{ m} \cdot \text{s}^{-1}$. In natural conditions TBPR may vary, depending on the bottom inclination and atmospheric forcing, e.g., $1.7 - 2 \cdot 10^{-2} \text{ m} \cdot \text{s}^{-1}$ in Lake Ladoga (Malm et al., 1993) and $1.2 \cdot 10^{-2} \text{ m} \cdot \text{s}^{-1}$ in Lake Ontario (Rodgers, 1966).

Estimates of the heat content change along cross sections perpendicular to TB confirmed the presence of horizontal heat transport from the near-shore warm zone to the TB zone (Malm et al., 1993). It was shown that the heat content change, compared to the surface heat flux, was higher in the TB zone and lower in the warm zone adjacent to TB. The model accounting for the horizontal heat transfer (Zilitinkevich et al., 1992) was found to better predict the propagation rate compared to earlier models considering only the surface heat flux as a source of warming (e.g., Elliott and Elliott, 1970).

The density (pressure) gradients on both sides of TB, under a geostrophic balance, form the so-called thermal wind flows, resulting in a strong cyclonic circulation in the warm zone and a weak anticyclonic circulation in the cold zone (see Figure 2 in Holland and Kay, 2003, p. 155). These flows, converging at TB, should damp the cross-frontal exchange. Results of experiments with

Thermal Bar, Figure 1 Scheme of the density-driven circulation in the near-shore zone of a lake during the thermal bar existence. Lines BB, AA, and B_1B_1 mark the near-shore warm, TB, and cold zones, respectively. (Taken from Tikhomirov, 1968, p. 169.)

natural tracers have shown that little mixing occurs between inshore and offshore waters, thus TB can be considered as a barrier separating warm and cold zones (Menon et al., 1971; Hubbard and Spain, 1973; Spain et al., 1976). Later observations (Gbah and Murthy, 1998; Rao et al., 2004) revealed that horizontal diffusion across the TB zone is consistently smaller than that directed along the front. The cross-frontal exchange coefficients are several orders of magnitude smaller than typical coastal values in the absence of TB.

Summary

The thermal bar is the unique physical phenomenon that should be studied further to better understand its nature, e.g., a clear formulation of the mechanism governing heat transport from the warm zone toward TB. Sergei Zilitinkevich (unpublished manuscript) suggested that it may occur due to baroclinic instability of geostrophic currents in the warm zone. Besides the strong effect on lake hydrodynamics, TB is every bit important from the standpoint of the impact on lake ecosystems, e.g., strong mixing in the TB zone, which leads to the longer life of all substances – including nutrients and pollutants – coming with inflow waters, in the lake proper. This in its turn may affect the seasonal development of plankton and a number of pollution events. Strong mixing may also accelerate sinking rates of newly formed organic matter and detritus, and then the former should intensify microbial activity in the bottom layers.

The limited space does not allow to give a comprehensive state-of-the-art review on TB studies performed. To get a better insight into the problem, a curious reader can be referred to the paper by Holland and Kay (2003). The authors nicely compiled most of observational, theoretical, and modeling studies carried out for the last 50 years, and suggested the outlook for further research.

THERMAL REGIME OF LAKES

Lars Bengtsson
 Department of Water Resources Engineering, Lund
 University, Lund, Sweden

Introduction

Heat is transferred to or lost from lake water through atmospheric exchange and with in- and outflowing rivers. There is also heat exchange with the bottom sediments. Since the depth varies over the lake, the heat exchange per unit mass is different in different water columns, which sets the water masses in an unstable condition

(baroclinic) and water movements are initiated striving to establish a stable condition (barotropic). The wind mixes the water so that the surface water is almost homothermal over the top meters. Further down, as a result of heating from the sun, when less and less solar radiation penetrates into deeper water, thermal stratification is established. Heating decreases the density of the upper layer. When the rate of atmospheric heat exchange with the water changes, convection within the water mass may be initiated and large water masses, maybe the entire lake water, will be part of the convective circulation.

Thermal character of lakes

Fresh water has its greatest density at 4°C, which means that in regions of cold winters, the bottom water is warmer than the surface water. Most lakes of the world are in temperate zones, where the winter temperature falls below 4°C. If not very shallow, these lakes are stratified in the summer with warm water at a temperature close to the air temperature at top and much colder water at the bottom. In the winter they may be ice covered through the winter or for short periods with water at or near 0°C at the surface and bottom temperature near 4°C at the bottom. The lake water turns over and mixes completely, all the water being 4°C, in the spring and in the autumn. These lakes are called temperate lakes or dimictic lakes. In a warm climate the lake water temperature never drops below 4°C. In these tropical or monomictic lakes vertical mixing to considerable depth or over the full depth occurs in the winter, when the surface temperature decreases to that of the bottom temperature. Lakes in the Arctic behave much as the temperate lakes, but in some of them the water temperature never reaches 4°C. Lakes that have year-round ice and never mix are called amictic lakes.

Development of vertical stratification

The dynamics of the temperature development in a temperate lake is described below starting from the homothermal situation in late autumn when the entire lake water is at the maximum density 4°C, which is the end of the autumn turnover period. From then on the water surface is cooled down mainly from longwave back radiation. When the weather is calm and the lake small, the surface temperature may drop to 0°C and ice may be formed already when most of the water is at 4°C. When there are strong winds acting on the lake a temperature profile with increasing water temperature from 0°C at the surface to 4°C or colder at the bottom develops before the lake freezes over. In not-so-deep wind-exposed lakes, the water temperature near the bottom may be very low and close to the surface temperature. It may also be that the lake only freezes over for short periods or not at all, and that the water temperature at the surface is some degrees above freezing point.

When there is a stable ice cover, there is no exchange with the atmosphere; the lake is almost insulated from the atmosphere. Instead, some heat is gained from the sediments, and the lake water becomes warmer throughout the winter. The temperature variation over the year of Lake Velen, Sweden, is shown in [Figure 1](#). When the ice disappears in spring, the whole lake water becomes homothermal at 4°C rather fast, because of rather intense solar radiation. The whole water mass mixes. This is the beginning of the spring turnover period. In the course of spring, the water is heated further and remains through wind mixing homothermal to considerable depth until the water is 6–10°C, although most of the solar radiation is absorbed near the surface. Thereafter the temporary gradients are too large for the wind to mix the water to

Thermal Regime of Lakes, Thermal Regime of Lakes, Figure 1 Temperature variation at different depth in Lake Velen, Sweden.

Thermal Regime of Lakes, Thermal Regime of Lakes,

considerable depth. The wind mixes the surface water only to some depth, so at lower depth the temperature gradient becomes quite sharp. A thermocline develops separating warm epilimnion water and cold hypolimnion water. The sharp temperature gradients reduce the vertical mixing between epilimnion and hypolimnion, which means that the gradient increases and becomes even sharper, which means that the thermocline becomes rather stable even when the winds are strong. An example of summer stratification is shown in Figure 2. The depth of the thermocline usually increases over the summer and the gradient becomes sharper.

In autumn the surface water is cooled down until the temperature difference between the epilimnion and hypolimnion is small and the thermocline can be broken by strong winds. There is mixing between surface and bottom water. The water is homothermal in this autumn turnover period. The entire lake continues to cool down and remain homothermal until the water temperature is 4°C. From then on the water at the surface cools down faster than the bottom water.

As already mentioned, in a tropical lake the surface water is always warmer or at the same temperature as the bottom water. A summer temperature profile is shown in Figure 3.

Horizontal gradients

Lakes which are not very large are horizontally rather well mixed. However, during days of intense solar radiation the water in shallow bays becomes warmer than the water far away from the shores. The temperature difference is minor, maybe 1°C, because convective currents striving to eliminate the temperature difference are induced. In

large lakes such as the North American Large Lakes or the Russian lakes Ladoga and Onega, a thermal barrier may develop, when near-shore surface water is heated to more than 4°C while the water far out in the lake is still below 4°C. Somewhere in between the water is at a maximum density at 4°C. Convection cells are initiated. Water is moving at the surface outward from the shore, mixes with colder water, becomes 4°C, and sinks toward the bottom due to its high density. Cold water from the main part of the lake moves inward, becomes colder, and when it is 4°C it sinks. The two convective cells meet where the temperature is at maximum density. No water passes this thermal barrier. This means that pollutants can be trapped at the shoreside of the thermal bar. The thermal bar moves outward in spring and early summer. In Lake Ladoga, it usually exists for more than a month. Temperature differences of more than 20°C have been observed.

If a lake consists of several basins, separated by sills, the bottom water is likely to have different temperatures except during the turnover periods.

Heat budget

The surface water temperature of a lake is close to that of the air, but the heat balance of a lake is determined by many processes. The heat budget is:

$$\frac{\Delta \text{HEAT}}{\Delta t} = \rho c_p \int A(z) T(z) dz$$

$$= A_0 (R + H_{\text{sens}} - H_{\text{lat}} + H_{\text{sed}}) + \rho c_p \Delta T Q$$

The first term is change of heat content over time, which is determined from the second term with ρ as density of water, c_p as the heat capacity, $A(z)$ is the lake area at depth z , and T is the corresponding temperature. On the right-hand side, A_0 is the lake surface area, ΔT is the temperature difference between inflowing river water and outflow with Q as the river inflow assumed to correspond to the outflow. H_{sens} is sensible heat flux into the lake, which is a function of the temperature difference between the atmosphere and the surface water. H_{lat} is the lateral heat loss from evaporation. The heat flux from the sediments, H_{sed} (or to the sediments in the summer), is significant only in ice covered lakes, where all the other fluxes are small. The net radiation R , is the dominating term and consists of four large fluxes:

$$R = R_{\text{sol}}(1 - \text{albedo}) + R_{\text{long}} - R_{\text{back}}$$

R_{sol} is the shortwave solar radiation, of which albedo time R_{sol} is reflected back to the atmosphere. The albedo is less than 10%; thus most of the solar radiation penetrates into the water. The longwave radiation, R_{long} , from the atmosphere can be estimated from the Stefan law. The emissivity depends on the cloudiness and the humidity of the atmosphere. On a clear day it may be 0.8 and on a rainy day close to unity. The back radiation, R_{back} , from the water surface is longwave radiation from the water and can be determined from the Stefan law with emissivity close to unity (0.97).

The shortwave radiation penetrates into the water and is absorbed at decreased rate as it penetrates to greater depth. In a low transparent lake, as most eutrophic lakes, all the shortwave radiation is absorbed not far from the surface. The penetration of the solar radiation can be determined, when the extinction coefficient, λ , of the water is known:

$$R(z) = R_{\text{sol}}(1 - \text{albedo}) e^{-\lambda z}$$

A warm summer day in southern Sweden with solar radiation of 600 W/m^2 during daytime when the air temperature is 25°C and the water temperature is 20°C , the sensible heat flux is about 50 W/m^2 , the latent heat loss 40 W/m^2 , the incoming longwave radiation about 370 W/m^2 , and the back radiation 420 W/m^2 resulting in a net flux into the lake of 560 W/m^2 , which in a 12-h period would heat a homothermal 5 m deep lake by about 1°C . During night there is no solar radiation, and since the air temperature usually is less than the water temperature, the sensible heat flux is a loss of heat. The net heat flux, if the night temperature is 17°C , is a loss of heat of about 120 W/m^2 , which would mean a reduction of the water temperature of about 0.2°C during the night.

THERMOBARIC STRATIFICATION OF VERY DEEP LAKES

Bertram Boehrer
 Department of Lake Research, Helmholtz Centre for Environmental Research – UFZ, Magdeburg, Germany

Definition

Thermobaric stratification refers to stable density stratification of natural water bodies, which results from the temperature dependence of the compressibility of water.

This feature can be observed in lakes of very low concentrations of dissolved substances. These lakes must be deep enough and situated in the appropriate climate zone.

Introduction

Although the compressibility of water is small, it permits a noticeable increase of in situ density under pressure, e.g., at great depth in lakes. Compressibility slightly decreases over the range of limnologically interesting temperatures. As a consequence, the temperature of maximum density T_{md} of pure water is shifted from 4°C to lower temperatures, by about 0.2 K at 100 m depth.

Thermobaric Stratification of Very Deep Lakes, Figure 1 Temperature profiles of thermobarically stratified lakes: *left panel* Tinnisjø, Norway, during (early) summer stratification above temperature of maximum density, T_{md} ; *central panel* Lake Baikal, Siberia, Russia, during (late) winter stratification with vertical transition through T_{md} ; *right panel* Lake Shikotsu, Hokkaido, Japan (From Boehrer and Schultze, 2008. With permission of American Geophysical Union).

Very deep freshwater lakes hence can have temperatures significantly smaller than 4°C (e.g., Yoshimura, 1936; Boehrer et al., 2008).

The T_{md} profile can be included in a depiction of measured temperatures against depth (see Figure 1). At any depth, moving away from T_{md} indicates decreasing density. In conclusion, left of the T_{md} profile falling temperatures toward shallower depths indicates stable stratification, while right of the T_{md} profile, the opposite is true. At the intersection with the T_{md} profile, a temperature profile must be constant for stability reasons. Hence, this is the maximum temperature in the profile of an ideal pure water lake (see Figure 1 central). Above and below the intersection, the temperature profile is stable on all depths.

As a consequence, such lakes can go from summer stratification into winter stratification without experiencing a full overturn. However, the small density gradients guarantee large-scale mixing within the water body. As a consequence, deep waters of thermobarically stratified lakes usually are well supplied with oxygen. During the transition into summer stratification, the temperature profile is kept close to the T_{md} profile over a wide depth range (Figure 1, right) with a nearly isothermal water body below, if horizontal differences are continuously negligible. In larger lakes, these features appear less clearly, and the deeper temperature profile is locked between T_{md} profile and a vertical line (Figure 1, left). In Lake Baikal,

the density stratification does not break at any time during the annual cycle. The stable density gradient is sustained by partial deep water renewal (Weiss et al., 1991; Wüest et al., 2005), i.e., by advection of cold water parcels from areas close to the side walls into the deep abyss.

TGP—Three Gorges Project

Introduction

China Yangtze Three Gorges Project (TGP), as one of the biggest hydropower-complex projects in the world, serves as the key project for improvement and development of Yangtze River. The name “Three Gorges” is based on three historically famous gorges, namely, Qutangxia, Wuxia, and Xilingxia, occupying about 200 km of Yangtze River. The dam is located in the areas of Xilingxia gorge, lowest one of the three gorges of the river, which controls a drainage area of 1 million square kilometers, with an average annual runoff of 451 billion cubic meters. The open valley at the dam site, with hard and complete granite as the bedrock, has provided the favorable

topographical and geological conditions for the construction of the dam. The first modern river development plan for the three gorges was drafted by Dr. Sun Yat-Sen in 1919 in his book *The international development of China* (Sun, 1919). The idea of constructing a huge dam was perhaps inspired by the successful story of the US Hoover Dam during the 1930s, and the official investigating and planning work was not even interrupted by the anti-Japanese war (1937–1945) and the following civil war. In 1992, The National People's Congress approved the dam with the result: out of 2,633 delegates, 1,767 voted in favor, 177 voted against, 664 forfeited, and 25 members did not vote. On December 14, 1994, the construction of the Three Gorges project was officially started with a three-phase project period ending at the year 2009. The dam body is located at Sandouping (coordinates: E111°0'36', N30° 9'48'), about 10 km northwest of Yichang city. A scenery photo of Qutangxia is shown in [Figure 1](#), and the general sketch of the dam location, the Yangtze River Basin together with China overview map is displayed in [Figure 2](#).

Some important features of the TGP project are described below, with the information source mainly from CTGPC (2011).

Flood control

The Three Gorges Reservoir is not the largest in terms of capacity in the world, and its reserved flood storage is calculated to be able to cut flood peak of 27,000–33,000 m³/s with a maximum peak of 116,110 m³/s. The standard water level of the dam is designed to be 175 m a.m.s.l. A bird's eye view of the dam can be seen in [Figure 3](#).

Three Gorges Project on the Yangtze River in China, Figure1 A view of three gorges (photo: Lars Bengtsson).

Three Gorges Project on the Yangtze River in China, Figure 2 Sketch of Yangtze River Basin and three gorges dam.

Three Gorges Project on the Yangtze River in China, Figure 3 Three gorges dam.

The flood control standard of the middle and lower reaches of the Yangtze, especially the Jingjiang Section, is to be upgraded from the previous level of preventing under-10-year floods to the current level of preventing 100-year floods. Some 15 million people and 1.5 million hectares of farmland in the Jiangnan Plain are protected from flood threats, and devastating plagues of massive death tolls caused by big floods can be averted. For comparison, some historical flood records of Yangtze River are listed in Table 1.

Power generation

The Three Gorges Hydropower Plant (TGHP) contains 26 turbine-generator units, each with an installed capacity of

700 MW. Additional six 700 MW units in the Right Bank Underground Powerhouse are under construction. Its total installed capacity amounts to 22,500 MW, and its expected annual average power generation accounts up to 84.7 TWH, so the TGHP ranks the biggest in the world with remarkable power generation benefit. At present, TGHP electricity is transmitted uninterruptedly to Central China, East China, Guangdong, and Chongqing with the maximum transmission range of 1,000 km (Table 2).

Navigation

Backwater of the TGP reservoir goes as far as to the southwest metropolitan area of Chongqing; therefore, it improves greatly the 660 km long waterway, which

Three Gorges Project on the Yangtze River in China, Table 1 Flood records of Yangtze River (1931, 1935, 1949, 1954, and 1998)

1931	The flood in 1931 struck an area of 130,000 km ² with 3.4 million hectares farmland and 1.8 million houses inundated, 28.6 million people affected, and 145,000 people killed, causing an approximate economic loss of 1.345 billion YinYuan (Silver Coin)
1935	The flood in 1935 hit an area of 89,000 km ² in the middle and lower reaches of the Yangtze River, affecting six provinces, Hubei, Hunan, Jiangxi, Anhui, Jiangsu, Zhejiang and ten million people, 1.5 million hectares of farmland inundated, and 142,000 people killed, causing an approximate economic loss of 0.355 billion YinYuan (Silver Coin)
1949	The flood in 1949 inundated 1.8 million hectares farmland, affected 8.1 million people, and caused the death of 5,699 people in the middle and lower reaches of the Yangtze River
1954	The damages caused by the flood in 1954 in the middle and lower reaches: 3.2 million hectares farmland and 4.27 million houses inundated, 18.9 million people and 123 counties and cities affected, 33,169 people killed, and the interruption of the Beijing-Guangzhou Railway for 100 days
1998	The flood in 1998 struck a large area of the Yangtze Valley. The country went all out to fight against the flood for nearly 3 months with large quantities of people and materials employed. More than RMB 13 billion worth of flood-fighting materials were dispatched from all around the country, and about 6.7 million people and hundred thousands of soldiers took part in the fighting. However, the flood still caused great losses with 239,000 ha farmland inundated, 2.316 million people affected and 1,526 people killed in the four provinces of Hunan, Hubei, Jiangxi, and Anhui

enables 10,000-tonnage fleets to navigate between Shanghai and Chongqing. It is expected that the annual one-way shipment capacity of the Yangtze passing the dam will be upgraded from 10 to 50 million tons.

World-scale project construction

The construction of the main structure of the Three Gorges Water Conservancy Complex includes the following works: rock-and-earth excavation of 102.83 million cubic meters, concrete placement of 27.94 million cubic meters, rock-and-earth refill of 31.98 million cubic meters, metal frame installation of 256,500 t, and installation of twenty-six 700 MW turbine-generator units. Except the index of rock-and-earth refill, all the indices are the biggest among water conservancy projects which are already built or under construction.

Main infrastructure

Dam: The TGP dam is a concrete gravity one, made of 14.86 million cubic meters concrete, the biggest amount in the world. The maximum flood discharge capacity of the dam is 116,110 m³/s, which is the largest in the world.

Power plant: The TGHP is of dam toe powerhouse. The installed capacity of a single unit and annual power generation of the TGHP are both the largest in the world. The transmission lines of two ± 500 kV DC circuits and eleven 500 kV AC circuits are also among largest in the world.

Ship lock: The following indices are among the world records: total water head of 113 m, inland river ship lock of five stages, a lock chamber's effective dimension of 280 m $\times$ 34 m $\times$ 5 m, inland river ship lock with capacity to accommodate 10,000-tonnage fleets, maximum operating water head 49.5 m for a gate of its water exchange system, maximum water filling-emptying amount of 260,000 m³, and maximum side slope excavation of 170 m in height.

Shiplift: Single-way and one-step vertical shiplift with counterweight is employed in TGP complex, consisting of upstream and downstream approach channels, upper and lower lock heads and ship chamber section with a total length of 6,000 m. The ship lock will allow a maximum 3,000-tonnage ship passing through. The ship chamber has outline dimensions of 132 m $\times$ 23.4 m $\times$ 10 m and effective water area in it is 120 m $\times$ 18 m $\times$ 3.5 m. The maximum lifting height is 113 m and total lifting weight is about 11,800 t. The TGP's shiplift ranks the first in the world in terms of the major technical parameters.

Metal works: The TGP metal works include 386 gates of various kinds, 139 hoists of various kinds, 26 penstocks, all of which add up to about 256,500 t. The overall work quantity ranks the top among the world's hydraulic projects. The following indices are also the biggest in the world: the penstock's inner diameter of 12.4 m, the maximum height of ship lock miter gate of 38.25 m, and operating water head of 36.25 m, single gate's weight of 850 t.

Resettlement

According to a 1992 survey, the TGP reservoir impoundment will inundate 632 km² of land, including 24,500 ha of farmland and citrus land, and affect the households of up to 850,000 people. It was planned to relocate a population of 1.13 million. As of June 2008, a total of 1.24 million residents were relocated, which can be compared with Hubei Province's 60 million and Chongqing's 32 million inhabitants. Relocation was officially completed on July 22, 2008.

Technology features

River close-off and concrete cut-off wall construction

The river close-off and the concrete cut-off wall construction are two key issues in building Phase-II rock-and-earth cofferdam with following characteristics:

River close-off on the main channel: The TGP river close-off on the main channel features deep river, large inflow, intense construction, tight timetable, navigability during the close-off process, deep surface layer above the levee foundation, and other difficulties. The TGP dam is situated at the backwater region of the Gezhouba Reservoir, and during the close-off the maximum water depth at the riverbed was 60 m. It is crucial to prevent levee break and keep the levee stable during the bank-off advance. The solution was to adopt the program of pre-leveling, upstream single levee blocking, simultaneous bank-off advance from both banks, and downstream follow-up advance.

Deep water cofferdam and concrete cut-off wall: The TGP Phase-II cofferdam was built to guarantee the year-around construction in the foundation pit during the TGP Phase II construction period. The biggest difficulty of the Phase-II cofferdam is the construction of concrete cut-off wall.

River close-off on the diversion channel: The construction used steel-framed rock cages and alloy steel nets to roughen the bottom and to increase the friction of the riverbed, so that rock barrier was formed to reduce the difficulty of close-off and to ensure the stability of the fill materials. Two parallel levees were built to take the waterfall off the diversion channel, the upstream levee holding two third of the waterfall, the downstream one holding one third. On November 6, 2002, the TGP diversion channel was successfully closed off.

Fast concrete placement

Total concrete placement in the TGP construction amounts to 28 $\times$ 10⁶ m³. Advanced equipment and fast concrete placement technology were applied to ensure the quality. Concrete placement on the TGP dam started in 1998 and finished during 2001.

High slope

High Side Slope of Three Gorges Ship lock: The double-way and five-step ship lock was excavated through the ridge to the left of the hydropower complex, with

upstream and downstream approach channels connecting to the Yangtze main channel. The total length is 6,442 m including 1,607 m for main body section. Continuous high slopes lie on both sides of the ship lock, with maximum height of 170 m, and the area of more than 120 m high slope extends for about 460 m long.

Metal Structures of Ship lock: The total weight of metal structures and M&E equipment of the ship lock is over 40,000 t. The ship lock is equipped with automatic computer control. On June 10, 2003, the TGP reservoir was impounded to elevation 135 m, and on June 16, 2003, trial navigation on the ship lock started. In 2004, some 34 million tons of cargo have passed the ship lock.

The generator units

The TGP generator units have the features of large quantity, big capacity, and big range of water head variability. The installed capacity of each TGP unit is 700 MW. Technology breakthroughs have been made in the following aspects during the installation: automatic welding on large stator assembly, lamination stacking of large stator in the field, welding and measurement of rotor roundness, and controlling roundness of rotor rim and plate. The installation of the units is among the top records. In 2003, a total of six 700 MW units were installed and put into operation.

Environmental protection

Clean energy

Compared to the coal-fired power stations with equivalent electricity generation, Three Gorges Power Plant will decrease emission of 100 million tons of CO₂, 2 million tons of SO₂, a remarkable amount of nitrogen oxide, wastewater as well as solid waste. It will bring a great benign influence in improvement of environment, especially preventing acid rain and greenhouse effect in East and Central China.

Conservation of natural scenery and cultural relics

Three Gorges reach stretches a river length of 192 km and is famous for its beautiful, natural landscapes and historical and cultural relics. Due to the rise of water level caused by the reservoir, some natural landscapes are submerged. However, since most mountains upon the banks are as high as 800–1,000 m, while the maximum water level of the reservoir is designed as 175 m, most of the natural landscapes are unchanged. On the other hand, 44 relics are influenced by the water level rise. Some of them, such as Baiheliang sculpture and epigraphs in Fuling, are among the first class on the national protection list of relics. Another five relics are among the provincial protection list. Some relics are preserved at its original location, or transferred or copied to new place, such as Baiheliang sculpture, Zhang Fei Temple, Shibaozhai and Qu Yuan Temple. The ancient tombs of the submerged area have been unearthed on the basis of survey.

Biodiversity

Forty-seven precious botanic species are identified as endangered and are among the national-level protection list. Most of them are found in the area higher than 300–1,200 m, which is believed not to be much influenced by the project. Twenty-six rare wild animals are among the first and second classes of national list of protected animals, most of them live in high mountain areas, and thus not influenced by the submerge. A number of national conservation zones are also set up to protect the wild animals and botanic species of this area.

Three Gorges dam has impacts on the migrating route and living locations of local fish species, especially *Chinese Sturgeon* (*Zhonghuaxun*, a large and rare fish species). This negative impact has been known when the Gezhouba dam was built in the 1980's. Some artificial breeding projects have been carried out with proven success and some hundred thousands of baby fishes are released into the river every year.

Water quality

The reservoir has a mixed influence on the water quality. The increased flow during the dry period should improve the water quality downstream and relieve the intrusion of saline tide in the delta area to East China Sea. On the other hand, the sewage discharged into the river is estimated to be over 1.35 billion tons/year, which is the most severe pollution source for the river. The great challenge is also that a reduced water flow rate is more vulnerable for pollution.

Earthquake and bank stability

Risks of induced earthquake has been discussed and debated for a long time, and extensive researches have been made on the issue involving rock mechanics, geological structure, and tectonic perspectives. Most of the TGP-related constructions are designed based on earthquake magnitude class VII. A 300–800 m deep-hole earth stress observation is carried out at dam and reservoir site, and the earthquake-intensive observation is made on some fractured zones around the dam. The results indicated that the geologic structure at the dam is stable. The possible maximum earthquake intensity is estimated to be below magnitude class VI. Bank stability issue is getting more attentions in line with water level approaching 175 m. It has been identified that more than 70 cases of landslide or debris flow have been reported since 1982 (Ye, 2005). The same report also estimated the number of high-risk, unstable places to be over 1,130 sites, an alarming increase that must not be neglected.

Sedimentation

The sediment ranks as a crucial issue for reservoir construction worldwide due to its impacts on the function and lifetime of reservoirs. A pre-study calculated the incoming sediment transport amounts to be 530 million

Three Gorges Project on the Yangtze River in China,
Table 3 Projected accumulation of sediments in Three Gorges reservoir (billion cubic meters)

Years	2012	2022	2032
Low-value scenario	1.75	3.57	5.34
High-value scenario	3.12	6.26	9.21

tons/year, which may influence both the navigation and the dam function.

Early sediment research on Three Gorges reservoir began already during 1960s and has a history of more than 30 years. The research is done based on prototype observation, and mathematic and physical modeling with reference to the construction of the as-built projects. One important measure to decrease the sediments is to restore the ecological balance of the upper-stream area by various methods to protect the environment and control the soil losses, and thus, decrease sediment inflow to Yangtze River and improve the water quality. In some recent studies (CRSRI, 2007; BOH-CWRC, 2007), it is estimated that the total amount of accumulated sediments for year 2012 will be between 1.75 and 3.12 billion cubic meters, and the details of their results are presented in Table 3.

Concluding remarks

In terms of technology and engineering advancement, and to some extent in economic development with its positive impacts, the Three Gorges Project is of great success. A much desired research would be on a thorough cost-benefit analysis, taking all environmental, ecological, and socioeconomic aspects into consideration in an integrated and holistic approach. Issues related to ecological and environmental degradation, water quality deterioration, biodiversity impacts, reservoir-induced disaster as well as human resettlement are still highly controversial (Probe International, 2011). These issues need to be carefully studied and addressed, not only by the government but also by the academic societies.

TITICACA LAKE

Lars Bengtsson¹, Rhodes W. Fairbridge (Deceased)

¹Department of Water Resources Engineering,
 Lund University, Lund, Sweden

Description

Lake Titicaca is the highest situated of the world's large lakes. It is partly in Bolivia and partly in Peru. It is covering 8,110 km². It is situated just south of the equator at an altitude of more than 3,800 m. There are more than 30 islands in the lake which reaches a maximum depth of about 300 m. The catchment area of Lake Titicaca including the lake itself is 56,000 km². The shore is highly indented, and the lake is divided into two lake basins, the upstream deep L. Chuquito and the smaller and shallow L. Huinamarca. The two lake basins are connected by the Tiquina Strait, which is in places only about 1.5 km wide. The depth of the smaller Lake Huinamarca is about 35 m. The surface level of Lake Titicaca is a mean 3 m above the narrow outlet sill at the border town of Desaguadero. The lake overflows to the southeast, into the Desaguadero River, which degenerates into the saline Lake Poopó and during very wet conditions further into the Salinas forming the TDPS system (Titicaca–Desaguadero–Poopó–Salinas system). The total area of the TDPS basin is about 144,000 km².

Geologically, Lake Titicaca lies in the complex gratin-faulted Altiplano, the Andean structural equivalent of the Basin-Range Province of North America and the various “median mass” structures of the Alpo-Himalayan orogenic belts. The Eastern Cordilleran side consists of much-folded Paleozoic geosynclinal sediments that are faulted against Cretaceous and other Mesozoic formations. The Altiplano depression is largely filled with late Tertiary and Quaternary lake deposits, volcanic deposits, and later by extensive alluvial fans.

There are no major cities around Lake Titicaca but numerous small Indian settlements. There are also extensive traces of the Inca and the Tiwanaku civilization. There are terraces indicating how the farmland was used. There are also clear signs of older and higher lake levels.

There is a swampy zone of totora fringed around Lake Titicaca. Further away, there are mountains. Some peaks reach 6,000 m a.s.l. There are six sub-basins within the Titicaca basin. The biggest one is the Ramis River basin extending over 15,000 km². The mean discharge of the Ramis River is 70 m³/s. The total inflow to Lake Titicaca is about 200 m³/s. The year can be divided into a wet summer period (November–March) and a dry winter

period (April–October). Although there are very high mountain peaks, only little precipitation falls as snow. The air temperature is rather constant throughout the year, with mean monthly temperature at lake level varying between 6°C and 12°C, but with extreme, 15–25°C, diurnal variations. The lake surface remains rather constant throughout the year at 12–13°C.

The outflow from Lake Titicaca is minor, about 30 m³/s, for such a large lake. The water balance of the lake is much dominated by the lake evaporation, about 1,300 mm. The outflow with the Desaguadero River corresponds to about 50 mm. The precipitation on the lake is about 800 mm, while the 200 m³/s river inflow corresponds to about 550 mm relative to the lake surface area. There have been short periods in modern time and extended periods in historical time when there has been no outflow. The lake level has even dropped so much that Lake Titicaca has been divided into two separate lakes. This happened 1,100–1,500 A.D., when the climate was dry for a very long time. The drought was devastating for the Tiwanaku civilization. The threshold level between the two Lake Titicaca basins is 19 m below the spill-over level of Lake Titicaca. The lake basin Huinamarca even almost dried out about 3,500 B.P. Today, there is a dam at the outlet at the town Desaguadero.

TRANSBOUNDARY WATERS: RIVERS, LAKES, AND GROUNDWATERS

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Description

Transboundary rivers and lakes play a significant part in the world's water resources. In the UNECE (United Nations Economic Commission for Europe) region, for example, in the 56 countries of the region, all but the three island states share water resources with one or more countries. Transboundary basins cover more than 40% of the European and Asian parts of UNECE and sometimes extend outside the region. They link populations of different countries, are a major source of income for millions of people, and create hydrological, social, and economic interdependencies between countries.

The interstate distribution of water presents a particular challenge to those countries with arid or semi-arid climates in Eastern Europe, Caucasus and Central Asia, and in Southeastern Europe. Problems inevitably arise and upstream–downstream conflicts sometimes exist regarding water sharing. Other examples of transboundary lakes and rivers include the rivers and

south to the Gaza Strip, an aquifer under the West Bank, and a pumped storage reservoir supply from the Lebanon's Litani River.

Another example is the 190 km long Shatt al-Arab waterway into which the Euphrates and Tigris empty at Al-Qurnah. It has been the subject of a longstanding frontier dispute between Iran and Iraq for some 400 years or more. An agreement exists whereby the thalweg of the waterway has been agreed.

The case of the transboundary rivers and lakes of the UNECE region has been the subject of a detailed study by the countries of the region. The study divided the whole region basically in two subregions: the Southeastern Europe (SEE) and Eastern Europe, Caucasus, and Central Asia (EECCA).

The UNECE assessment of transboundary rivers, lakes, and groundwaters is the first ever in-depth report produced on the subject in the UNECE region.

The report covers 140 transboundary waters and 30 transboundary lakes as well as 70 transboundary aquifers located in Southeastern Europe, Caucasus, and Central Asia. The inventory of the study, reproduced here, is contained in [Tables 1–8](#) where first-order basins are presented in *bold*.

TROPIC LAKE CLASSIFICATION

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

The world's lakes were formed by various means, but many by movement of the earth's crust, or by glacial or volcanic action. Some may have a surface area of a few square kilometers to thousands of square kilometers (for example, the Caspian Sea). Many lakes are aged as much as 20 million years (Aral Sea, Baikal, Caspian, Prespa, etc.).

However interesting age and formation may be, placing lakes in a class system is probably best by considering lake quality. In this respect a trophic classification is generally preferred to lake water mixing and circulation capability or fish community.

Trophic concept

The richness in nutrients of the lake is the basis for addressing the classification as follows:

- (a) Oligotrophic
- (b) Eutrophic
- (c) Mesotrophic
- (d) Dystrophic

Oligotrophic lakes

The nutrient-poor lakes or oligotrophic contain very low growth productivity except some plankton and some large fish. The clarity of the lake is such that a Secchi disk may have a reading of 10 m. In oligotrophic lakes, therefore, there is little production of organic matter few suspended algae, the phytoplankton yielding low chlorophyll averaging about 1.7 mg per cubic meter and little organic bed sediment. On the other hand, consumption of oxygen is low, leaving abundant oxygen throughout the depth.

Oligotrophic lakes have clean water, no weed problems, but poor fishing, and seldom in good agriculture land.

Eutrophic lakes

Compared to oligotrophic lakes, eutrophic lakes are rich in nutrients with high productivity, producing large numbers of phytoplankton which, as algae, tend to cloud the lake water. Because of this the Secchi disk gives much lower readings compared with oligotrophic of the order of 2.5 m. Eutrophic lakes produce much zooplankton and small fish which feed on the zooplankton.

A characteristic of eutrophic lakes is the depletion of oxygen in lower depths usually below the thermocline (below, say, 5.5 m, Kevern et al. 1996).

Trophic Lake Classification, Table 1 Phosphorus and chlorophyll concentrations and Secchi disk depths characteristic of the trophic classification of lakes

Measured parameter		Oligotrophic	Mesotrophic	Eutrophic
Total phosphorus (mg/m ³)	Average	8	26.7	84.4
	Range	30.–18	10.9–95.6	16–386
Chlorophyll (mg/m ³)	Average	1.7	4.7	14.3
	Range	0.3–4.5	3–11	3–78
Secchi disk depth (m)	Average	9.9	4.2	2.45
	Range	5.4–28.3	1.5–8.1	0.8–7.0

Because of the large concentration of phytoplankton, eutrophic lakes have chlorophyll concentrations averaging 14 mg per cubic meters and phosphorus concentration averages of 80 mg per cubic meter.

These lakes are often shallow with weed beds but usually having large numbers of fish due to the available plankton and benthic organisms.

The transition stage between oligotrophic and eutrophic lakes is the mesotrophic lake. The growth of plankton is intermediate, and the range of values of phosphorus and chlorophyll and Secchi disks overlap. Average values for all three concepts is given in the Table 1 which is taken from Wetzel (1983), and it can be seen that there are no fixed values of phosphorus or chlorophyll concentrations nor of Secchi values.

Dystrophic lakes

A dystrophic lake develops from the accumulation of organic matter from outside the lake. A tree-lined catchment where leaves are able to drop into the lake brings subsequent humic acids. Dystrophic lakes have usually low pH values but has clear but colored water resulting from organic acids. Such lakes are normally poor in calcium and plankton production and in fish population.

It is clear that a trophic classification of lakes may have many exceptions and interpretations and, in some cases, is dependent on the use to which the lake is put.

TSUNAMI EFFECT ON A COASTAL LAKE IN INDIA

Kamala Kanta Satpathy¹, Ajit Kumar Mohanty¹, Sudeepa Biswas², M. Selvanayagam², Santosh Kumar Sarkar³

¹Environmental & Safety Division, Indira Gandhi Center for Atomic Research (IGCAR), Kalpakkam, TN, India

³Department of Marine Science, Calcutta University, Kolkata, India

Introduction

Kalpakkam (12°34'N Lat. and 80°11'E Long.), situated on the east coast of India about 80 km south of Chennai (Figure 1), is known for existence of nuclear facilities, such as Madras Atomic Power Station (MAPS) and Prototype Fast Breeder Reactor (PFBR). The entire site covers approximately 1,500 ha. It is bestowed with a number of natural water bodies in the form of backwaters and lakes. One of them is a tiny brackish water lake (Kokilamedu lake) situated on the isolated northeastern side of the campus. It covers an area of 0.75 sq km during monsoon period, and the spread shrinks to 0.5 sq km during summer. The average depth is about 1 m and has a maximum depth of 3 m. The lake provides a conducive environment for the waders as well as for other aquatic and terrestrial fauna that inhabit the rich flora in and around the lake. A 50-m width strip of sand bream, which is covered by *Casuarina* and *Pandanus*, forms the barrier between the lake and Bay of Bengal. Occasionally, seawater intrusion into the lake takes place during high tides. Apart from the avian guests who visit during winter, the endemic avian fauna of the lake is comprised of some important bird species like pelicans, painted storks, black headed ibis, etc., along with fishes and amphibians. This lake has attracted the attention of ecologists due to two important events that have taken place during the last decade. During May 1995, a massive fish kill was observed, and this was attributed to natural eutrophication coupled with anoxic condition and high temperature (Venugopalan et al., 1998). The other important event which has affected the lake ecology is the mega December 2004 tsunami, which completely inundated the lake with seawater and brought massive amount of sediment from the sea into the lake (Satpathy et al., 2007, 2008). An increase in seawater influx was noticed after the event of the tsunami, which narrowed the sand barrier and destroyed the vegetation between the lake and the sea. Sketchy data available prior to tsunami revealed that the lake characteristic was close to a freshwater one. In spite of the above two events, no systematic and comprehensive scientific investigation on the lake ecology was available till August 2006. Considering the ecological importance of the lake, a scientific investigation with respect to various

ecological parameters has been initiated since September 2006, with the following objectives:

- To create a baseline data on physicochemical parameters for future impact studies
- To assess the change that has taken place after tsunami by comparing the available pre-tsunami information.
- To suggest and implement appropriate measures to improve and restore the ecology of the lake

In the present entry only the first two objectives have been addressed.

Based on the climatology of this location, the whole year is divided into three seasons: (1) post-monsoon/summer (February–May), (2) pre-monsoon or south-west monsoon (June–September), and (3) northeast monsoon (October–January). The northeast monsoon is active in this area, and a bulk (70%) of rainfall occurs during this period. The average rainfall here is about 1,200 mm.

Methodology

Water samples were collected once in a week for a period of 1 year (September 2006–August 2007) from a fixed location in pre-cleaned polythene bottles and analyzed for various physicochemical and biological parameters. DO was estimated following standard methods (Grasshoff et al., 1983). pH measurements were carried out by a pH meter (CyberScan PCD 5500). Conductivity of the water samples were measured by a conductivity meter (CyberScan Con 100). The dissolved micronutrients such as, nitrite + nitrate, ammonia, silicate and phosphate, along with total nitrogen (TN), total phosphorus (TP) and chlorophyll-*a* were estimated by following standard methods (Parsons et al., 1984; Grasshoff et al., 1983). Statistical analyses such as correlation matrix and cluster analysis were carried out by using XLStat 2008 software. Similar work on water quality characteristics carried out during June 1994–May 1995 (unpublished) was used as pre-tsunami data to assess any change.

Results and discussion

The results obtained were pooled into monthly average values to get a clarity of the seasonal variation of the physicochemical parameters and chlorophyll-*a* and are reported here.

pH

The lake water was found to be alkaline throughout the year with pH > 8 in almost all the observations. It ranged from 7.6 to 8.9 with the monthly average value ranging from 8.00 ± 0.36 in February 2007 to 8.60 ± 0 in September 2006 (Figure 2a). Highest and lowest values of pH were observed during the period of high and low salinity (conductivity) regime of the lake waters. pH values between pre- and post-tsunami showed that the values have increased marginally during post-tsunami period (Figure 2b). Inundation of seawater, which is more alkaline

Tsunami Effect on a Coastal Lake in India, Figure 1 Kokilamedu lake showing sampling location.

in nature, into the lake during the tsunami has pushed the pH up. Moreover, there has also been sporadic incursion of seawater into the lake as the barrier between sea and the lake has been thinned down during the tsunami. Positive correlation ($p \geq 0.000$) obtained between pH and salinity (conductivity) (Table 1) corroborates the above observation and explanation.

Conductivity

The lake represented a typical brackish water character with conductivity ranging from 7.80–18.41 mS during the post-tsunami period. The monthly values varied between 9.90 ± 0.57 during January and 18.03 ± 0.54 during August (Figure 2a). Values of conductivity gradually decreased from September to January and then increased up to August. It showed a clear unimodal

oscillation with a peak during pre-NE monsoon and a fall during the monsoon period. During post-monsoon and summer the conductivity remained comparatively low due to the rain water received during the monsoon period. The extensive green foliage available near the lake coupled with location of the lake at low elevation possibly was responsible for reduced evaporation leading to observation of relatively low conductivity even during summer. Reduction in water level was noticed during the late summer and pre-monsoon leading to increase in conductivity. One of the interesting observations is that, the conductivity has increased significantly from 1.83 mS during May 1995 to 18.41 mS during August 2007. Seawater intrusion during the December 2004 tsunami and occasionally thereafter could be the reason for the above observation. However, typical

^b $p \geq 0.005$

^c $p \geq 0.01$

coastal water conductivity (~ 55 mS) was never observed in spite of seawater intrusion. Conductivity values of the lake just after Tsunami, which might have been very close to typical seawater conductivity, has been reducing since then as a result of the precipitation received during post-tsunami period.

Dissolved oxygen

DO values ranged from 5.43 to 7.12 mg L^{-1} , which showed that the lake water is well oxygenated. The monthly values of DO ranged from 5.67 ± 0.16 mg L^{-1} in May to 6.84 ± 0.20 mg L^{-1} in February (Figure 2a). As expected, relatively high values were observed during the monsoon

and post-monsoon period, which showed that freshwater influx from land runoff during monsoon, is one of the causative factors in variation in oxygen content of the lake water. Strong negative correlation ($p \geq 0.000$) of DO with salinity (conductivity) further supported the above observation. A moderate negative correlation ($p \geq 0.005$) was found between DO and chlorophyll-*a*, which showed that photo-synthetically re-sealed DO was negligible, and instead, the consumption of DO was higher in the presence of high algal biomass. This could be due to the near eutrophic conditions of the lake that support high algal growth, producing a high amount of organic matter in the form of senescent algae. A comparison of the present DO content with that of the pre-tsunami period (ranged from 5.0 to 7.4 mg l⁻¹) showed a marginal reduction, attributed to the increased salinity (conductivity) as solubility of oxygen and salt content are inversely related.

Nitrite and nitrate

Nitrite and nitrate were estimated together, considering the fact that nitrite is the most unstable nitrogenous nutrient that shows a wide range of fluctuations in aquatic ecosystems. The values ranged from 0.10 to 67.77 $\mu\text{mol l}^{-1}$ with monthly average values ranging from 0.38 ± 0.17 to $36.55 \pm 15.77 \mu\text{mol l}^{-1}$ during July and September, respectively (Figure 2a). A gradual decrease in concentration of these nutrients was observed from September to November, and an increase was noticed during the monsoon period. Wide fluctuation in inorganic nitrogen is well known in aquatic bodies and particularly in shallow ones. Nitrite, being the intermediate oxidation state between ammonia and nitrate, can appear as a transient species by the oxidation of ammonia or by the reduction of nitrate and also often released into the water as an extracellular product of the planktonic organisms (Santschi et al., 1990). However, nitrate is thermodynamically the most stable form of combined inorganic nitrogen in well-oxygenated waters. Variations in nitrate are generally a result of biologically activated reactions. Quick assimilation by phytoplankton and enhancement by surface runoff result in a large-scale spatiotemporal variation of nitrate in the aquatic medium (Zepp, 1997). Relatively high concentration of these nutrients during monsoon could be attributed to the nitrate-rich surface runoff getting into the lake. A significant increase (50-fold) in concentration of these nutrients was observed between the present values and that of the pre-tsunami concentration (0.24–0.64 $\mu\text{mol l}^{-1}$).

Ammonia

Ammonia concentrations ranged from 0.17 to 179.69 $\mu\text{mol l}^{-1}$, yielding monthly average values ranging from $1.71 \pm 0.23 \mu\text{mol l}^{-1}$ to $55.89 \pm 83.55 \mu\text{mol l}^{-1}$ during September and June, respectively (Figure 3). A significant variation was observed in its concentration throughout the year. A gradual increase was noticed from September to April with the peak concentration being observed during June, after which the concentration got

Tsunami Effect on a Coastal Lake in India, Figure 3 Seasonal variation in ammonia, total nitrogen, total phosphorous, and chlorophyll-*a* of Kokilamedu Lake during the study period (2006–2007).

reduced. In the present study, ammonia significantly contributed to TN concentration, as observed from its strong positive correlation ($p \geq 0.000$) with TN. Being the chief excretory product of the aquatic invertebrates, ammonia is also well known as a nutrient, which is preferred over nitrate by the phytoplankton community in certain environmental conditions. Thus, concentration of ammonia in the aquatic environment can be significantly affected by excretory release and utilization by phytoplankton (Gilbert et al., 1982). The irregular trend observed could be attributed to the above-mentioned two factors, along with the fact that in aquatic medium, it also gets oxidized and reduced to other forms; and hence, fluctuates widely (Sankaranarayanan and Qasim, 1969).

Total nitrogen

Concentration of TN ranged from 9.13 to 310.84 $\mu\text{mol l}^{-1}$. Monthly average values ranged from 31.70 ± 31.72 to $129.69 \pm 56.93 \mu\text{mol l}^{-1}$ (Figure 3). Relatively high TN concentration was observed during the pre-monsoon and summer than that of monsoon period. Significant decrease in the water level of the lake during pre-monsoon (to ~ 40% of the total volume present during monsoon)

leads to increase in concentration of dissolved nutrients. Positive correlation between TN and salinity (conductivity) supports the above observation. Among nitrogenous nutrients, contribution of ammonia to TN was more significant than the other two nitrogenous nutrients in this environment.

Silicate

Concentrations of silicate ranged from 17.33 to 247.50 $\mu\text{mol l}^{-1}$. Although no particular seasonal trend could be observed, its concentrations were relatively high during post-monsoon and summer. It did not show significant correlation with any nutrients except a strong positive correlation with chlorophyll-*a*. It is reasonable to presume that the phytoplankton population of the lake is perhaps dominated by species other than diatoms, which do not use silicate. Silicate concentration in aquatic environment can fluctuate due to several processes such as its biological removal by phytoplankton, especially by diatoms and silicoflagellates (Aston, 1980); factors like physical mixing of fresh water (Purushothaman and Venugopalan, 1972); adsorption of reactive silicate into suspended sedimentary particles (Lal, 1978); chemical interaction with sediment (Aston, 1980); and coprecipitation with humic compounds and iron (Stephns and Oppenheimer, 1972). Thus, the wide variation observed is not unusual. Present silicate values (ranged from 37.62 to 78.86 $\mu\text{mol l}^{-1}$) showed a fourfold increase as compared to the pre-tsunami observations. Release of silicate from the sediment which got deposited from sea during tsunami to water column takes place through a complex process wherein salinity and pH plays a significant role. Thus, the present environmental conditions might be favoring the benthopelagic coupling, resulting in the enhanced nutrient concentrations of the lake water.

Phosphate and total phosphorous

Phosphate and TP values ranged from 0.46 to 8.31 $\mu\text{mol l}^{-1}$ and 0.55 to 9.59 $\mu\text{mol l}^{-1}$, respectively. Concentration of phosphate and TP exhibited almost a similar pattern of variations. Both phosphate and TP showed strong positive correlations with nitrite + nitrate and TN; this showed that there was some external source of phosphate which could be in the form of bird droppings, as has been described by Venugopalan et al. (1998), that came along with the surface runoff during monsoon period. Though the peak was observed during September, relatively increased values of phosphate during December to March (monsoon and post-monsoon) supported the above-mentioned speculation of external input. Marginal increase in silicate with salinity (conductivity) is a result of impact of evaporation during the summer and pre-monsoon, as described earlier. Substantial increase in phosphate concentration (eightfold) was noticed during the post-tsunami period (pre-tsunami range 0.13–1.09 $\mu\text{mol l}^{-1}$). Phosphate-rich sediment brought

from sea during tsunami gets released to the water column depending on pH and salinity, as is known, and thus has hiked its content.

Chlorophyll-*a*

Chlorophyll-*a* values showed a well-marked variation and ranged from 2.24 to 115.78 mg m^{-3} during the present study, which indicated that the lake is highly productive in nature. The lowest value obtained during December could be due to the impact of freshwater input from land runoff during the northeast monsoon period. Moreover, relatively low salinity during this period also could have retarded the growth of brackish water phytoplankton species. Similarly, the higher value during April could be attributed to the optimum condition of phytoplankton growth with relatively high salinity, temperature, and pH. Chlorophyll-*a* was found to be positively correlated ($p \geq 0.005$) with salinity (conductivity) and pH. Moreover, during late summer, the decrease in water level of the lake concentrates the algal components. The chlorophyll-*a* values in combination with phosphate concentration is generally used to assess the trophic structure of the lake (Forsberg and Ryding, 1980). In the present study, the lake showed various trophic structures, such as mesotrophic, eutrophic, and hypertrophic, depending up on the different seasons of the year.

Cluster analysis

Results of cluster analysis showed that the same months were involved in their respective clusters in both similarity and dissimilarity clusters (Figure 4a, b). The months September and October formed one cluster, which represented the pre-monsoon period. November to March which represents the monsoon and post-monsoon period of this locality formed another cluster, which showed that there existed a similarity in environmental conditions of the lake during these months. The third cluster was formed from April to August, which represented a period corresponding to the summer and summer monsoon (southwest monsoon). The above observations showed that the lake environment is significantly affected by the northeast monsoon (winter monsoon) which is active in this part of India. The entire 1-year period is characterized by three clusters depicting three environmental conditions coinciding them.

Conclusion

High nutrient and chlorophyll-*a* concentrations observed implied that the lake is nearly eutrophic in nature. Pre- and post-tsunami water quality characteristics showed a drastic change in its environmental features, particularly the enhancement of nutrients. Since this lake is secluded from any kind of anthropogenic interventions and is of shallow depth, the internal nutrient loading from wind-induced resuspension could be another source of nutrient enrichment. In addition, sizable quantity of cattle excreta (about

Tsunami Effect on a Coastal Lake in India, Figure 4 Dendrogram of similarity (a) and dissimilarity (b) clusters among the different months.

200 numbers move around the lake) would have also contributed to the nutrient loading of the lake by a way of land runoff during monsoon period. The increasing water salinity (conductivity) is one of the main concerns which showed that the environment that existed nearly a decade ago is changing in the general process of transformation from a coastal shallow water lake into a salt marsh. In view of this, efforts are underway to deepen the lake by desilting it

and planting fruit-bearing and shady trees to improve the avian population. Although increased nutrient contents and decreased lake depth are substantial during the post-tsunami period, no fish kill has been observed, and the lake has not been eutrophic, as observed earlier (Venugopalan et al., 1998) at much lower nutrient concentration and higher water column. This suggests the need for further investigation on its ecology.

Coastal Lagoons

TURBIDITY CURRENTS IN RESERVOIRS

Josef Schneider¹, Gabriele Harb¹, Hannes Badura²

¹Institute of Hydraulic Engineering and Water Resources Management, Graz University of Technology, Graz, Austria

²Verbund Hydro Power AG, Vienna, Austria

Introduction

Impounding and retaining water in reservoirs has been one essential basic development for the onset of human civilization. An important aspect, though, which has been

known for a long time and which has lately gained in importance, is reservoir sedimentation. Statistics show that more than 50% of streams and rivers are dammed, which implies that the greater part of transported sediment, in fact some 80%, is trapped in reservoirs. This corresponds to a volume of about 8–16 km³ (Lemperier and Lafitte, 2006). Morris and Fan (1998) quantified the world's total sediment deposit at between 15 and 40 Gt p.a.; this corresponds to between 0.5 and 1 t of sediment per 1,000 m³ of water. White (2001) estimates that more than 0.5% of the total reservoir storage volume is lost worldwide due to reservoir sedimentation. The costs for restoring these losses and rebuilding the dams can be estimated at US\$13 billion a year (Palmieri et al., 2003). Considering the different scales of reservoirs, it can be stated that for small reservoirs, the sediment budget can be managed within the framework of the operation rules and is considered as a routine job (e.g., water intakes). For reservoirs defined by great capacity with large dead-storage spaces, sedimentation is a long term rather than an acute phenomenon. The medium-sized reservoirs are characterized by sedimentation problems that need to be counteracted with adequate measures. Further, since these reservoirs are often operated on a daily or weekly basis, the relatively small available storage is intensively utilized. The most commonly applied methodologies for handling reservoir sedimentation are dredging and flushing activities (Palmieri et al., 2003). Dredging is costly and spatially a highly limited measure. Reservoir flushings are effective, but may, in fact, have substantial ecological impacts. Increased sediment concentrations downstream of dams may cause direct damage to fish populations and the macrozoobenthos while clogging off interstitial spaces in the gravel bed and evolving, thus, into substantial long-term problems.

Density currents

The force of gravity and small differences in density of water keep a density current in motion. In the case of lakes and reservoirs, the current is generated between different parts of the same fluid.

The differences in density can be triggered by:

- Temperature
- Salinity
- Concentration of suspended sediment (turbidity)

Figure 1, beneath, is a satellite image showing the mouth of the River Rhine in Lake Constance. The plunge point area (1) is clearly visible, and the plunging density current proceeding in a north-western direction from the mouth (2) is also clearly discernible. Schoklitsch (1935) described already the plunge of the River Rhine into Lake Constance, called “brech” by the local population, whereas that of the River Rhône into Lake Geneva was locally termed “la bataillière.”

Turbidity currents

Density currents are generally understood to refer to stratified flows caused by differences in density, whereas *turbidity currents* are specific forms and usually refer to stratified flows caused by differences in sediment concentration.

Depending on the density conditions in the lake or reservoir, Morris and Fan (1998) differentiate between three different turbidity flows:

- Top flow (overflow)
- Intermediate flow (interflow)
- Bottom flow (underflow)

Figure 2 depicts these possible flow situations plus the so-called plunge point or plunge line; this defines the

Turbidity Currents in Reservoirs, Figure 1 Satellite image of lake Constance showing plunge point and density current (Courtesy of Google, 2007).

location where the inflow can be witnessed to disappear from the surface. Accumulations of driftwood and other flotsam caused by backflow have often been observed at such points.

Thus, turbidity currents are special density currents that arise from the plunging of the sediment-laden river water into the clear water of a lake or reservoir.

Understanding turbidity currents is of great importance as these may serve to throw light on the movement and, especially, on the deposition of fine sediment in reservoirs and lakes. The location of sediment deposition may be anticipated, thus, not only due to such classical phenomena as the reduction in flow velocity with its consequential sinking processes, but also due to the occurrence of density currents. A turbidity current developing at the bottom of a reservoir and moving toward the dam within the former streambed will come to a halt when it reaches the dam and will consequently deposit the suspended material. A phenomenon observed in many reservoirs is that fine sediment is mainly deposited near the intake structures in the vicinity of the dam.

The stability of turbidity currents depend on the geometry and slopes of a lake and on the differences in density of water. Turbidity currents can be dissolved, either continuously or in an enforced and accelerated manner on their way down.

Fundamentally, such density currents might be vented through a reservoir, if the local conditions are favorable, in order to minimize or even prevent the deposition of fine sediment. Buckley (1911) already described the occurrence of stratified flows caused by concentration differentials in the Indian storage pools as well as of the possibility of draining the turbid flood water flowing at depth by opening bottom outlets. Successful venting has also been described by Morris and Fan (1998) in the Lost Creek Reservoir in Oregon, USA, the Steeg Reservoir in Algeria, the Sefid-Rud Reservoir in Iran, and the Sanmenxia Reservoir in China, where it has been possible to sluice out more than half of the total sediment load through the reservoir during a flood. Xiaoqing (2003) mentioned the venting

Turbidity Currents in Reservoirs, Figure 2 Plunge point and possibilities of turbidity current development (Ford and Johnson, 1983).

of a turbidity current through the Nebeur reservoir in Tunisia, preventing, thus, more than 60% of the sediment from depositing. Some density currents have been observed to cover distances of more than 100 km of a reservoir on their way to the dam. One such example is Lake Mead, where a density current had been identified with a length of 150 km (Engez, 1961).

Reports on density currents were published by Cook and Richmond (2004) and Bühler et al. (2004). Molino et al. (2001) did not only describe density currents, but carried out also 2D numerical calculations. Firoozabadi et al. (2003) simulated density currents in physical model tests. Venting of density currents resulting from temperature gradients at the Whiskeytown Reservoir, California has been observed by Knoblauch and Simões (2000). Turbidity currents were studied by the EPFL in Lausanne, Switzerland (e.g., Oehy et al., 2000; De Cesare and Schleiss, 2004) with the aim of dispersing them in order to arrive at a more uniform sedimentation process in the Luzzzone reservoir and in Lake Lugano.

Example Soelk reservoir

The Soelk reservoir is located in the Grosssoelk river which is a southern tributary of the river Enns in Upper Styria, Austria. The natural catchment has an area of 140.9 km², and the three diverted catchments amount to a total of 244 km². The annual mean precipitation has been assessed around 1,194 mm; the mean flow of the Grosssoelk river at the reservoir is 5.23 m³/s; the annual flood has been calculated to be 42 m³/s; the calculated 10-year flood is 100 m³/s; and the 100-year flood is 165 m³/s (HL, 1975). The catchment area includes about 37% of forestland, 28% of alpine meadowland, and about 21% of land under agriculture – pastures and grassland (Bieringer, 1983). The remaining areas are rock, debris, roads, etc. The geology is typical for the Lower Tauern area, consisting mainly of the so-called gneiss complex. The gneiss compound material of the Central Alps is resistant, but the less stable mica schist is also prevailing in some places.

The Soelk power station, operated by Verbund Hydro Power AG (VHP), was built between 1976 and 1978. The design flow is 30 m³/s for a nominal head of 212 m. The maximum, or bottleneck, capacity is 61 MW, and the annual energy is 221 million kWh (Schneider, 2002).

The reservoir is created by an arch dam 39 m in maximum height and 129 m long at the crest. The reservoir is 1.3 km long and has a usable storage of 1.4 million cubic meters. A check dam 7 m high with a crest level of 899 m a.s.l. provided at the upstream end of the reservoir prevents coarse sediment from entering the reservoir. The auxiliary structures are all erected in the vicinity of the dam. The flood discharge is designed over the crest; the lowest outlet is situated on the right-hand bank, slightly downstream from the power intake. The flip-bucket outlet of the Donnersbach diversion is between the lowest outlet and the dam, and the outlet of the Klein-Soelk diversion is to the left of the reservoir.

In addition to the presence of a plunge point identified at the upstream end of the Soelk reservoir, there have been other indications suggesting the potential occurrence of turbidity currents. Sedimentation has its center near the dam, which may be the evidence of deposition from a turbidity lake caused by turbidity current. In addition, the design of the Soelk reservoir is excellently suited for the development of turbidity currents, as the reservoir is relatively short and straight and has a substantial gradient, the valley being V-shaped with steep slopes, and the bottom outlet being situated on the low level in the vicinity of the dam. Numerical analyzes indicate as well the occurrence of turbidity currents (Schneider, 2002, 2004).

In order to verify the assumption that turbidity currents occur in the Soelk reservoir and to obtain the best possible data for further numerical analysis, instruments were installed at five locations to measure hydrological parameters, which will be briefly described here and illustrated in Figure 3 (see also Badura, 2002; Habersack et al., 2002; Troy, 2006; Wachter, 2008; Gruber, 2009).

A temperature and turbidity probe (90° infrared backscatter) has been provided 1 km upstream from the reservoir head, near an existing discharge gauge, owned by the operator VHP with GSM data transmission (MP1).

The measuring device MP2 had been installed slightly downstream from the plunge point location. At about 7 m from the reservoir bottom, a facedown Acoustic Doppler Profiler (ADP), which measures flow velocities in three dimensions, had been installed. This ADP works at a frequency of 0.75 MHz and is capable of measuring cells with having a minimum size of 80 cm. Beneath these, two multiparameter probes had been located, 1 and 2.5 m above the bottom, measuring temperature, conductivity, and turbidity. The data were transmitted to the bank by cable and then via GSM. Near the data logger, a webcam has been observing the gauge.

A third instrument location (MP3) had been located immediately above the intake to the bottom outlet (Figure 4). It measures the same parameters as MP2; the ADP here had been installed directly on a cantilevering steel girder. Next to it was another tensioned vertical steel rope carrying the two multiparameter probes at 1 and 4 m above the bottom. These data were also transmitted to the surface by cable and then via GSM. A further webcam had been installed at this point.

The fourth measuring station (MP4) had been located a few hundred meters downstream from the dam, recording water temperature and turbidity. To portray an accurate overview of the reservoir in question, it has to be stated that there is usually no flow downstream the dam under dry weather conditions and that the probe measures data, thus, can only be collected in the case of spillway discharge or with the bottom outlet open. The fifth measuring station (MP5) had been installed downstream the turbine outlet at the powerhouse for measuring the turbidity of the water going through the turbine.

Figures 5 and 6 exemplify the flow situation in the reservoir during flood events. Figure 5 gives an impression of

Turbidity Currents in Reservoirs, Figure 3 Measuring points at the Soelk reservoir, location and parameter.

the load curves and of the turbidity in different locations. It is evident that the inflowing water (MP1) shows the first peak. Due to the flow times between the different probes, a temporal different appearance of concentration peaks could be observed. The time lag between MP1 and MP2 has been 50 min and between MP2 and MP3, about 2 h.

Furthermore, a decrease of the peak has been visible in the vicinity of the dam. This indicates the intermixing of turbid and clear water. MP5 shows a similar characteristic as MP3, whereas the values for MP5 were generally higher than for MP3. This can be explained by the basic influence of the river Soelk that affects the probe.

Turbidity Currents in Reservoirs, Figure 4 Measuring point 3, probes and photo taken during installation, with the reservoir level drawn down.

Turbidity Currents in Reservoirs, Figure 5 Load curve of suspended sediment concentration at different locations during a flood in July 2007.

However, the inflowing turbid water into the reservoir could be monitored specifically. The flood event in July 2007 was insofar characterized that the turbine had been shut down and the bottom outlet was opened for a short time at July 10. Between 17:00 and 18:30, the penstock had been shut and the bottom outlet was opened (until 19:30). Unfortunately, due to problems with the probe MP4, the first data are missing. However, it can be evidenced that the turbidity was relatively high due to the released water via spillway in the beginning. When

the bottom outlet had been opened, a rapid increase of the turbidity could be observed. After shutting the bottom outlet, these high concentrations disappeared again. The increase of turbidity at MP5 during the shutdown of the turbine can be explained by the influence of the river Soelk once more.

The measurements of velocities at MP3 orthogonal to the opening of the bottom outlet are depicted in Figure 6. Changes in flow velocities as well as flow directions could be observed. The shutting of the penstock and the opening

Turbidity Currents in Reservoirs, Figure 6 Velocities at MP3 during the flood event in July 2007 in y -direction (orthogonal to the opening of the bottom outlet).

of the bottom outlet can be seen here quite impressively. However, the velocities were very low and therefore the turbidity current was not fully developed.

Detailed studies regarding the economy involved in venting turbidity currents through the Soelk reservoir (Putz, 2007) have shown that this method of reservoir management is especially useful when water is discharged over the spillway as in the case of opening the bottom outlet; this entails not to minor water losses.

Summary

This entry summarizes the physical phenomenon turbidity currents described in literature as well as the field measurements taken in a European reservoir for verifying turbidity flows. It discusses also in consequence one possibility of reducing reservoir sedimentation. The example of the Soelk reservoir in Austria has been used for demonstration to prove that measurements in nature can give evidence that turbidity currents may flow downstream to the dam. As inflows to the reservoir and, hence, suspended sediment concentrations, have been low during the measurement campaign, there has been no evident event of venting turbidity currents. However, the identification of high sediment concentrations along the reservoir down to the bottom outlet during several events has substantiated the assumption that it is possible to vent turbidity currents through the Soelk reservoir during major events. Turbidity measurements above the reservoir head, directly below the plunge point region and at the bottom outlet, have revealed a time lag in the turbid flow peaks. This observation has been supported by the results of conductivity and temperature measurements. In addition, 3D measurements of flow velocity in the plunge

point region and at the bottom outlet brought forth satisfactory results even with low flow velocities.

In terms of statistics, the spillway operates six times a year. Thus, it should be possible to open the bottom outlet during floods in order to provide the basis for developing an important contribution to sustainable and environmentally compatible sediment management.

Acknowledgments

The authors wish to express their gratitude to the *FFG – Austrian Research Promotion Agency*, which has financed the greater part of the project *ETS – Influence of turbidity currents on reservoir sedimentation – venting through a bottom outlet as an alternative* (Contract Number 810977). Many thanks also to the economic partner and co-financer *Verbund Hydro Power AG*.

Introduction

In the sandy state of Rajasthan, there are numerous lakes in Udaipur. Surrounded by hills, Udaipur is located in a saucer-shaped basin over an area of 475.85 km² in the Aravalli range, at an elevation of 573 m. The city is interspersed with three serene lakes, Pichola, Fateh Sagar, and Udai Sagar, and is well known as the “City of Lakes.” These gleaming lakes enhance the beauty of the town. The two most scenic and famous lakes of the city are Lake Pichola and Lake Fateh Sagar. Lake Fateh Sagar lies to north of Pichola and was built by Maharana Jai Singh, but it got the name of Fateh Singh who rebuilt its dam. Both the lakes are breathtakingly beautiful, and one can take a cruise on their waters. The sunset over these lakes is momentous to be cherished.

Pichola is fed by Sisarma, a non-perennial river. Gorana-ki-nal, a dam upstream the Aravalli, was connected to the Sisarma river recently. Fateh Sagar has a very small catchment of its own and is fed by Bari tank and Chota and Bada Madar. The overflow from the Bada and Chota Madar tanks merge with the Ahar river. The Ahar river feeds Udai Sagar several kilometers downstream. The overflow from Bari tank directly merges with Fateh Sagar. The overflow from Pichola flows into Fateh Sagar, and the overflow from Fateh Sagar flows into the Ahar through a canal before it enters Udai Sagar. With this

web of lakes and wells, most of the rain falling within the Udaipur basin was kept within the basin itself, with very little losses.

In the past few decades, catchment destruction has increased the rate of siltation, jeopardizing the very existence of the lakes. Deforestation in the hills surrounding Udaipur and in the adjoining forests of Mewar region has meant that each year’s monsoon washes down tons of silt into the lakes. It has been estimated that the capacity of Pichola is reducing every year by 0.93%, and that of Fateh Sagar, by 1.16%. There was a silt trap between the Madar tank and Fateh Sagar at Thur-ki-pal village, but it has now broken. The silt now enters into the Fateh Sagar. Urbanization around the lakes has turned them into receptacles for organic matter and domestic wastes.

Approximately 60,000 people live around the lakes, and nearly 60 hotels dot their peripheries. Domestic sewage and wastewater from the hotels is let into these lakes. Domestic solid waste of about 20–25 t/day is also dumped close to the lakes. This finds its way into the lakes during the monsoons. Besides, people living around the lakes continuously attempt to extend their personal property by encroaching upon the lakes. The 73 ghats on Lake Pichola are used by the public for bathing and washing, which includes infected linen from hospitals. A large amount of detergent goes into the water, increasing its phosphate content. The poor quality of drinking water here is resulting in the high incidence of water-borne diseases such as typhoid, paratyphoid, amoebic dysentery, colitis, diarrhea, and viral hepatitis. The pollution has also practically wiped out the major carps, leaving only minor carps, minnows, and puntius.

Between 1978 and 1982 a partial sewage system was constructed (without a sewage treatment plant) to cover 30–35% of the population around the lakes. However, due to certain design limitations and improper maintenance, the system does not function and raw sewage flows directly into Pichola. Besides, water treatment plants,

which have a capacity of 24.1 million liters per day (mld), generally treat 31.8 mld – handling an overload of 32%. A number of cracks in the filter beds result in suspended solids escaping into the drinking water.

Lake Pichola

Pichola Lake is a beautiful expanse of water that surrounds the islands of the Lake Palace Hotel (Jag Niwas) and Jag Mandir. The backdrop of the overlooking City Palace gives this lake its name – Pichola. Apart from this there is also another origin to its name. It is said that the name comes from the nearby small village of Picholi and was originally created early in the fifteenth century by a local Banjara tribesman who transported grain. Legend has it that, finding his bullocks could not ford the stream at the southern end, he built a dam across it, over which the animals could cross.

In 1560, a year after Maharana Udai Singh II began building his new capital of Udaipur around the shore, he strengthened the dam and greatly enlarged the lake. Apart from the two large islands, there are several smaller ones, among them are Arsi Vilas, which is a haven for birds, and a platform, Natni-ka-Chabutra, which has its own legend. At the northern end of the lake is the old town with its ghats and a ceremonial ghat where the Gangaur Festival is celebrated with fireworks and illuminations. The height of the dam is 15.24 m in the Badi Pol area.

Along its eastern shore sprawls the massive City Palace. South of this is the hill known as Machhala Magra, where part of the old city wall and the small fort of Eklinggarh could still be seen. Beyond this is the Shikarbadi Hotel, once the Khasi Odi, or hunting lodge, of the Maharanas. At full tank level the Pichola Lake covers an area of almost 1.5 sq km. The beautiful Lake Pichola is surrounded by hills, palaces, temples, and bathing ghats. It is the largest of all Udaipur Lakes.

Fateh Sagar Lake

The pride of the City of Lakes, this lake was constructed toward the north of Lake Pichola and was built by Maharana Jai Singh, but it got the name of Fateh Singh who rebuilt its dam. Fateh Sagar is the second of Udaipur's four man-made lakes. During 1678, Maharana Jai Singh (1680–1698), who had already constructed the famous Jaisamand Lake southeast of Udaipur, excavated this new small lake. It lies immediately to the north of and connected by a canal to Pichola Lake, which had been established by Maharana Udai Singh II a century earlier.

Fateh Sagar is 2.4 km long, 1.6 km wide, and 11.5 m at its deepest point; when full, it covers an area of about 1 sq km, being fed by the Ahar (Berach) river. It is possible to drive around the complete circumference of the lake via Moti Magri Road, Fateh Sagar Drive, and Rani Road, a serpentine route that provides beautiful views of the lake as well as the encircling Aravalli Hills. The main causeways to the lake are from Pichola Lake, Madar Lake, and Badi Lake. It has three inlet channels and an overflow channel for the rainy season.

Two centuries after its construction, a severe storm and heavy rainfall collapsed the old eastern embankment causing loss of life and considerable damage, especially to the nearby, lower-level Sahelion-ki-Bari gardens. In 1889, to prevent further such flooding, Maharana Fateh Singh reconstructed the embankment. Later that same year, the Duke of Connaught, third son of Queen Victoria, laid the new embankment's foundation stone, and the lake was renamed Fateh Sagar. This reconstructed northeastern embankment has three names, the Pal, the Drive, or Connaught Bund (embankment or breakwater). Along it is the entrance to Moti Magri hill, on the summit of which is a landscaped park with the Maharana Pratap Memorial.

Three small islands grace Fateh Sagar, the largest being Nehru Park, a popular garden island with a restaurant and zoo, which is reached by inboard motor boats from the bottom of Moti Magri Hill. The Government of Rajasthan made the second island into a public park with a spectacular water-jet fountain, and the third houses the Udaipur Solar Observatory, the largest in Asia. A peaceful spot not far from the city center, the lake is a popular leisure area for picnics and water recreation in hired pedal boats. Because of Fateh Sagar's blue waters and its backdrop of green hills, it is often referred to as the second Kashmir, an epithet often given to all of Udaipur.

UNITED KINGDOM, LARGEST LAKES

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

The United Kingdom has a population of some 63 million and an area of 244,000 km² of which inland waters cover an area of over 3,000 km² giving a high proportion of population to areas of land and inland waters.

It is estimated that there are some 50,000 lakes in the United Kingdom of which over 31,000 are in mainland Scotland alone. These are mainly found in the Highlands where, in the Counties of Sutherland and Caithness, they form an area commonly known in scientific geography as the "Flow Country," since their density forms a large proportion of the surrounding land area. In general these highland lakes may only have local names, often in Gaelic and most are shallow and under 5 ha (0.05 km²). The larger of these are of glacial formation.

In Scotland lakes are known as *lochs* and sometimes *lochans*. *Loch* is a Scottish Gaelic word for a lake or fiord from the Irish *lough* which itself is formed from Irish Gaelic *loch* pronounced "loc."

In Wales, "lake" is translated from the Welsh as "Llyn."

The following tables provide a summary of the largest lakes in the United Kingdom. Their location is shown in [Figure 1](#).

UNITED STATES: PRINCIPAL FRESHWATER LAKES

Reginald W. Herschy

Hydrology Consultant, Reading, UK

Introduction

The United States has some 250 freshwater lakes that are known to have surface areas of 10 sq miles (26 km²) or more. Nearly 100 of these are in Alaska and 100 in Minnesota, Wisconsin, Michigan, New York, and Maine. Thirty-four freshwater lakes, exclusive of the Great Lakes, are known to have maximum depths of 250 ft (76.2 m) or more. Twenty of these are in Alaska, and Alaska undoubtedly has more lakes of that depth which have not been sounded.

In actual fact, the amount of water stored in natural lakes in the United States, even exclusive of the Great Lakes, is much greater than the amount stored in artificial lakes (reservoirs). With the exception of the Great Lakes, however, the economic value of natural lakes is surpassed by that of reservoirs. Natural lakes are best known in the United States for the recreational advantages they afford.

Note: Pyramid Lake, a saline lake in Nevada (see p. 14) is about 280 ft deep at its present level, according to M. T. Wilson (written communication, 1962)

^aSounded by US Coast and Geodetic Survey in 1959. In 1886, Mark Kerr measured 1,996 feet at approximately same point. According to Hutchinson (1957), Crater Lake is the second deepest lake in the Western Hemisphere, exceeded only by Great Slave Lake in Canada, depth about 2,010 ft^bRussell (1885, p. 72)^cInterim report on southwestern Alaska, by the Corps of Engineers, 1954^dLess than 10 sq miles^eSounded by US Geological Survey^fWolcott (1961)^gFenneman (1938)^hW. D. Smith, Northwest Science, December 1939ⁱSounded by K. N. Phillips, August 10, 1940

In view of the opportunity offered by lakes for the public good, a Lakes Study Commission was created to review anticipated recreational demand at lakes and developing recommendations for enhancing recreational use of these facilities.

United States: Principal Freshwater Lakes, Table 3 Principal saline lakes

Lake	Present area (sq miles)	Remarks
California		
Salton Sea Owens	350 dry at times each year since 1943	About 650 sq miles at highest stage in 1905–1907. 110 sq miles in 1872, prior to diversions from Owens River; 35 sq miles in 1943
Mono Goose (also in Oregon)	76 About 100	Maximum, 89 sq miles in 1919. Maximum, 186 sq miles, 125 in California and 61 in Oregon; overflowed into Pitt River in 1869 and 1881; dry in 1930; 150 sq miles in 1958
Eagle	41	Some questions as to whether Eagle Lake should be considered saline or freshwater. It has no surface outlet (Martin, 1962), but since 1924 it has been tapped by tunnel to Willow Creek. Salinity is considerably less 1,000 ppm, according to California Dept. of Water Resources. During period 1895–1925 lake rose to highest level since at least 1650 (Harding, 1935); rise believed due to closing of subterranean outlet by earthquake in 1890 (Antevs, 1938)
Honey	Dry	90 sq miles in 1867, possibly higher in 1890; dry in 1903; high in 1904; dry in 1924. Contained some water April 1958 to September 1960, and early in 1962
Louisiana		
Pontchartrain	625	These lakes are connected with the Gulf of Mexico, and are subject to tidal fluctuations
Sabine (Louisiana and Texas)	95	These lakes are connected with the Gulf of Mexico, and are subject to tidal fluctuations
Calcasieu	90	These lakes are connected with the Gulf of Mexico, and are subject to tidal fluctuations
Maurepas	90	These lakes are connected with the Gulf of Mexico, and are subject to tidal fluctuations
Salvador	70	These lakes are connected with the Gulf of Mexico, and are subject to tidal fluctuations
Nevada		
Pyramid	180	Maximum size, 220 sq miles. Low until 1860; reached extreme high level in 1862 and 1868 or 1869; nearly as high in 1890; began to drop in 1917 (Hardman and Venstrom, 1941)
Walker	107	Maximum size, 125 sq miles
Winnemucca	Dry	Maximum size, 180 sq miles. Dry in 1840, but began to fill shortly thereafter (Zones, 1961). According to Russell (1885), the lake rose more than 50 ft and approximately doubled its area between 1867 and 1882. Was 87 ft deep in 1882. Dry since 1945
Carson	Nearly dry	Maximum size, 41 sq miles. A few water-filled pot holes remain. Once called South Carson Lake; received flow of Carson River before Lahontan Reservoir was built
Carson Sink	Dry	A shallow playa some 250 sq miles in area shown on some maps as a body of water. Russell (1885) called it North Carson Lake. Dry in 1882, but probably has had some water at times since. Once received water from both Carson and Humboldt Rivers
Ruby		Maximum size, 37 sq miles. Shown as swamp on recent maps of Army Map Service and Nevada Dept. of Highways
Franklin		Maximum size, 32 sq miles. Shown as swamp on recent maps of the Army Map Service and Nevada Dept. of Highways
North Dakota		
Devils	24	140 sq miles in 1867; 70 sq miles in 1883; 45 sq miles in 1900; 10 sq miles in 1940. Since 1940 lake has been rising
Oregon		
Malheur and Harney	Probably dry	Malheur, the larger of the two lakes, overflows into Harney, which has no outlet. Maximum combined size, 125 sq miles. Reported dry in 1931; high in late 1950s; about 1 sq miles in 1961, and expected to go dry in 1962
Goose (see California)		
Abert	52	Maximum size, 60 sq miles. Dry in 1930 or thereabouts, but fairly high in 1958
Summer	Probably dry	Maximum size, 70 sq miles. Nearly dry in 1961

United States: Principal Freshwater Lakes, Table 3 (Continued)

Lake	Present area (sq miles)	Remarks
Silver	Dry	Maximum size, 15 sq miles. Dry in 1961. Because of the transient nature of the lake, the water – whenever there is any – is relatively fresh; hay is raised on the dry lake bed
Warner	Probably less than 10	A series of shallow lakes; combined area about 30 sq miles in 1953, a wet year, estimated from Army Map Service map based on aerial photographs taken in 1953. Present lakes are all that is left of Pleistocene Warner Lake, which covered about 300 sq miles and was about 270 ft deep
<i>Utah</i>		
Great Salt	About 1,000	Maximum size since 1851, 2,400 sq miles in 1870s; minimum, 950 sq miles in October 1961; seasonal high in 1962 was 1,050 sq miles in June
Sevier	Dry	Maximum size, 125 sq miles; has been dry for several years

United States: Principal Freshwater Lakes, Figure 1 The number of lakes in each state in numerical order from Table 1.

The following tables taken from the USGS Circular 476 (see Bue, 1963) is primarily a glossary of lakes in the United States that have a surface area of 10 sq miles (25.9 km²) or more.

Table 1 lists, by US states, the names and surface areas of lakes above 10 sq miles given by counties except those in Alaska where locations are given by latitude and longitude.

Table 2 includes lakes of 250 ft (76.25 m) or more in depth, although there may be deeper lakes in Alaska and elsewhere noted since the Circular was published in 1963.

Table 3 gives a list of the principal saline lakes.

Volume of lakes

The USGS estimate the volume of the lakes in Tables 1 and 2 from the equation:

$$\text{Volume} = \frac{1}{3} \text{maximum depth} \cdot \text{surface area}$$

In general, the equation gives results which are too low but satisfactory for making comparisons.

URBAN LAKES AND PONDS

Jesper Persson

Landscape Management, Design and Construction,
Swedish Agricultural University, Alnarp, Sweden

Definition

An urban lake is an inland body of surface water surrounded by an urban environment and larger than a pond, while an urban pond is an inland body of surface water surrounded by an urban environment, but smaller than a lake.

A retention pond is a pond which has a permanent pool and is more or less vegetative. It treats storm water by removing pollutants from runoff through sedimentation, biological uptake, and plant filtration, but it also has a storage volume above the permanent pool that reduces runoff peaks caused by rain events. Synonyms to retention pond are wet pond, wet basin, or sediment pond.

A detention pond is a pond which only temporarily contains water, since it dries out between rain events. Its main purpose is to detain water and thereby reduce runoff peaks caused by rain events. Synonyms to detention pond are dry pond, dry basin, or detention basin.

History

The use of storage pools in gardens has been seen in cities at least since the establishment of the Old Kingdom in Egypt around 3000 BC. Public parks and gardens with water works were also widespread throughout the ancient Greek and Roman cities. In later times, urban lakes and ponds became more common in connection with rapid urbanization and the establishment of urban parks during the 1800s. The fundamental ideas behind this trend lay in the Romantic movement and the concept of public health. During the late 1700s, a reaction against the Enlightenment arose in Romanticism, which regarded nature as divine and a source of spiritual vitality for human beings. This was followed in the 1800s by the advent of many urban environmental problems related to industrialization – such as poor waste disposal and the pollution of air and drinking water. Thus, to improve people's health and give them fresh energy, urban parks and water environments were laid out (Plumptre, 1993; Benton and Short, 1999).

However, between 1975 and 1985 the view of these urban lakes and ponds changed. Now the issues were not only recreation and aesthetics, but also ecology and environmental technology. In the USA and Germany, numerous experiments were made to purify water with the help of ponds and wetlands. This contributed to the development of the subject of ecological engineering, as well as to a paradigm shift in landscape architecture and the introduction of the theory of sustainable landscape development (Campbell and Ogden, 1999). This new view was also promoted by the Rio Declaration of 1992, which emphasized an integration of economic, social, and ecological values. The result today is that urban ponds are an important component of sensitive or sustainable urban drainage. In stormwater management, urban ponds and lakes ideally provide, in addition to aesthetic values and greater possibilities for recreation, improvement of water quality and reduction of runoff peaks. The water in cities, including stormwater, is to be regarded as a resource and not a problem.

Essential concepts

There is no common consensus about what distinguishes ponds from lakes, but most often size is used as a criterion. There seems also to be a general idea that ponds may lie between 25 and 20,000 m² (Williams et al., 2003). An urban pond as well as an urban lake can receive water from streams and groundwater, and by direct urban runoff through pipes. The outflow may be natural in the form of a stream, or artificial by pipes. Most urban ponds and lakes are constructed, and are strongly affected by their urban surroundings as regards both water quality and hydrological load.

There is sometimes confusion about the difference between a pond and a wetland, even though this seldom leads to any problem. There are numerous definitions of a wetland, but also of how it differs from a pond. Two basic outlooks can be discerned. One considers a pond as a special case of a wetland. Then "wetland" becomes an umbrella term including ponds and shallow lakes. An example is the Ramsar Convention which uses a broad

definition of wetlands including everything from lakes, rivers, and estuaries to wet grasslands and peatlands. The other outlook is to consider the difference between wetlands and ponds as a matter of degree in the amount of permanent pool, i.e., vegetation. If the degree of permanent pool is 100% it is a pond, and if 0% it is regarded as a wetland. Noteworthy is that a “pool” in a garden context sometimes is interchangeable with “pond.” Here, a pool is always considered to be something constructed, and ideally with a fountain and a geometric form – circular, oval, or polygonal – whereas a pond often has a natural shape with waterside planting.

Urban lakes and ponds as examples of a multiple-use approach

Urban lakes and ponds have many functions that city planners, ecologists, landscape architects, and civil engineers try to combine in a multifunctional manner, so that social, biological, and technical values can be developed together.

Probably the most obvious aspect of social value is recreation. People can walk or jog along the waterside, have picnics, or just relax. If the water freezes during winter, skating is often very popular. In some lakes and larger ponds it is possible to fish or row and in some others, usually smaller ponds, stones are added for children to jump on; see [Figure 1](#). Urban lakes and ponds located in parks also add aesthetic values as well as improved microclimates during warmer weather. Then there may be educational values; e.g., school classes can visit to do nature studies (Campbell and Ogden, 1999). The popular Yamaguchi Park in Pamplona, Spain, has an urban pond shown in [Figure 2](#). This park, with its pond designed by Japanese landscape gardeners, also has a symbolic value since it constitutes a bond between the cities of Yamaguchi and Pamplona.

The characteristic of aquatic environments is that they are quickly colonized by organisms. This means that even small urban waters can acquire a high biodiversity. There are examples from Europe where red-listed species have been found after only a few years in newly built ponds. It is mainly insects that have the ability to fly as adults and colonize new environments, but also nonflying organisms such as flatworms and freshwater isopods will establish themselves quickly. However, in order for amphibians to benefit, the water must be fish-free and nearby land areas must be suitable. Good wildlife corridors will further support the establishment of new species and genetic exchange between populations. The most important wildlife corridor for aquatic organisms stretches along open watercourses. Building culverts in a watercourse is therefore detrimental to this spread. In addition, seeds and phyto- and zooplankton can hitchhike with birds when they visit the new ponds in search of food (Campbell and Ogden, 1999; Kadlec and Wallace, 2009).

Lakes, due to their size, have several advantages over ponds when it comes to reducing pollutant loads and flow peaks. Therefore, in stormwater management, an effort

Urban Lakes And Ponds, Figure 1 An example of a simple way to improve recreational value. Husie Mosse Malmö, Sweden. Photo Pekke Kärppä.

has been made to improve pond and wetland efficiency. The basic principles for pond design in terms of technical function, on the other hand, are contradictory. To improve the pollutant removal efficiency it is preferred to have as large a permanent pool as possible, whereas to detain water it is preferred that the stormwater pond has a large detention volume, i.e., it is better if the pond is empty when the rain begins. Normally, the outflow from a detention pond is designed to empty the pond within 1–2 days. To balance these two goals, an additional pond design has been developed that combines the detention and retention ponds – named an extended detention pond. Important factors that affect the sedimentation process and thereby also the pollutant removal capacity are

Urban Lakes And Ponds, Figure 2 Yamaguchi Park in Pamplona, Spain, illustrates an example of an urban pond.
Photo Jesper Person.

particle size, hydrological load, pollutant concentration, vegetation, pond surface area, and pond hydraulics, which, e.g., describe how water moves within a pond, effective volume, the amount of dead zones, and short-circuiting. It may be added that most of the pollutant removal occurs between rain events and not during an event (Mays, 2001; Persson and Wittgren, 2003).

Environmental problems

Urban lakes and ponds receive polluted water, since they are located within an urban environment with parks and paved surfaces. It is generally known that there are several pollutants which contribute to urban environmental problems, such as:

- Metals (such as lead, copper, cadmium, and zinc) and hydrocarbons such as oil and PAH that originate from traffic, which are all toxic and dangerous for fauna and vegetation as well as humans
- Sediment which increases turbidity and originates from eroding banks and road sanding
- Leakage from polluted soil, e.g., landfill and industrial areas
- Airborne pollutants such as sulfur and nitrogen that come with precipitation
- Chlorides from road salting
- Litter that degrades the beauty of surface waters and threatens wildlife
- Algae growth, which often occurs in ponds that are shallow and exposed to the sun, have little vegetation and low water circulation, and receive fertilizers

- Organic materials such as leaves and grass, which add to the load of oxygen-demanding material, and thereby reduce oxygen concentrations
- Herbicides and insecticides, which originate from management of urban green land such as parks, private gardens, playing fields, golf courses, and road verges

Current controversies

Today most people see stormwater ponds as sustainable water management and a good example of urban development. But there are also those who regard stormwater ponds as hazardous places since they expose humans and animals to polluted water, and not as adding ecological values (National Research Council, 2001). There are also those who highlight the risk that small children can drown, thereby creating a dispute not only about fens, but also about the existence of urban ponds per se. Another controversy is that there can be several problems connected with detention basins. That is, they may kill forests, destroy habitats for woodland species, or require permanent maintenance – and when they fail, they can actually create more damage than they were designed to prevent, such as flooding due to blocked outlets (Mays, 2001). It has also been found that a detention pond is little used by wildlife, in contrast to ponds with a permanent pool (Campbell and Ogden, 1999).

Summary

Urban lakes and ponds became ever more common when cities grew during the rise of industrialism. At first, their main purpose was to add aesthetic qualities in parks and

improve the health of city dwellers. Since the 1970s and 1980s, there has also been a vision that these systems can purify water and prevent flooding. In principle, lakes and ponds are distinguished by their size: a lake is larger than a pond, which has an area between 25 and 20,000 m². In park contexts, a pond is distinguished in turn from a pool: whereas a pond often has a natural shape with water-side planting, a pool often has a geometric form. Today, urban lakes and ponds are planned and developed so that they acquire multifunctional values. These range from social values such as recreation and aesthetics, or biological values such as diversity, to technological values like the fact that the systems can clean water and reduce flooding.

V

VENTING TURBIDITY CURRENTS IN RESERVOIRS

Josef Schneider¹, Gabriele Harb¹, Hannes Badura²

¹Institute of Hydraulic Engineering and Water Resources Management, Graz University of Technology, Graz, Austria

²Verbund Hydro Power AG, Vienna, Austria

Description

Turbidity currents are generally understood to stand for stratified flows in lakes or reservoirs caused by the differences in density of suspended sediment concentrations between the inflowing and the standing water.

Turbidity currents occur mainly during floods since high discharges and suspended sediment concentrations are often a consequence. What is significant about turbidity currents is the sudden submersion of the clear stagnant water by the turbid water, the plunge point. Subsequently, the turbidity currents layer at the bottom of a reservoir, continue moving toward the dam within the former streambed, and come to a halt when reaching the dam and transform in a so-called submerged muddy lake. The barrier of the dam causes the suspended material to settle, which is in many cases undesirably.

The probability of turbidity current events is a matter of correlation between hydrological and sedimentological predispositions, as well of the topography of a reservoir, e.g., its geometry, which is decisive for the tolerance of turbidity currents; since the reservoir has to be relatively short and straight with a substantial gradient, the valley should be V-shaped with steep slopes with the bottom outlet situated at a low level in the vicinity of the dam.

Fundamentally, such turbidity currents could be vented through a reservoir by opening low-lying gates like bottom outlets at precisely adjusted moments. The advantage of venting turbidity currents is in many cases the

desired reduction of sedimentation, the less frequent necessary variant of flushing, and the more ecological justifiable way to release sediments out of a reservoir.

According to respective literature, venting turbidity currents through reservoirs has been dealt with so far mainly in Asia, America, and Africa. Efficiencies between 50% and 80% have been documented concerning the prevention of inflowing sediment deposition, and that is very representative.

Not all reservoirs are suitable for supporting the venting of turbidity currents. This is predominantly a matter of whether turbidity currents occur at all along the reservoir bottom, and most importantly, whether they do not dissolve on their own after a certain distance. It is conceivable that turbidity currents mix with clear lake water along their way and reduce, therewith, their concentration differential, on one hand or on the other hand, it is also imaginable that they remobilize already-deposited fine material along their path and become, thus, consequentially stronger, heavier, and more accelerated. Knowledge about the flow situation, travel time between inlet and bottom outlet, as well as sediment concentrations, and temperature distributions in the reservoir are essential to assess the feasibility of venting.

Measurements of turbidity performed by the authors in a European Alpine reservoir showed that high sediment concentrations could be observed at the inlet of the bottom outlet during floods. It is recommendable, therefore, to open the bottom outlet in such a case, especially when the spillway is in operation, and thus potential water losses for the original purposes of the reservoir have not to be considered.

Acknowledgments

The authors wish to express their gratitude to the *FFG – Austrian Research Promotion Agency*, which has financed the greater part of the project *ETS – Influence of turbidity*

currents on reservoir sedimentation – venting through a bottom outlet as an alternative (Contract Number 810977). Many thanks also to the economic partner and co-financer Verbund Hydro Power AG.

[Turbidity Currents in Reservoirs](#)

VICTORIA LAKE

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

Lake Victoria is the largest lake in Africa (68,800 km²), and the most important freshwater resource for the people living in its vicinity. The lake forms, together with Lake Kyoga and Lake Mobutu Sese Seko, an estimated reservoir of 3,200 km³ of freshwater. The sole outlet of Lake Victoria is the River Nile leaving the lake near Jina (Uganda), flowing through the Lakes Kyoga and Mobutu Sese Seko and contributing on average 14% of the flow in the combined White and Blue Niles as measured at Aswan. The flow of the Nile is relatively constant due to the natural regulatory effect of the three equatorial lakes.

Changes in the water balance of the lakes are of major importance not only to the riparian countries, but also to the countries north of these lakes, Sudan and Egypt, which receive water from the Upper Nile basin besides the Blue Nile from Ethiopia. In addition to increased damage to lake-shore interests in Kenya, Uganda, and Tanzania, large fluctuations in lake level result in variations in flow of the Nile which is of major importance to Egypt, a densely populated country totally dependent on the continued flow of its largest river for drinking water and for power generation. Significant jumps in flow of the river are related to higher water levels in Lakes Victoria and Mobutu. Increases in River Nile flows during 1960–1964 and 1977–1980 were clearly related to the rise in level in Lake Victoria in those periods. International agreements between Egypt and Uganda and between Egypt and Sudan were concluded as early as 1929. Regulation of the Nile has been a major issue since the early decades of this century to all the countries concerned. Water from the lake is used for irrigation purposes in all three countries.

Fisheries

Fishing and related post-harvest processing have been a very important economic activity in and around Lake Victoria, and a rapidly growing population of more than eight million people in its catchment area depends on the lake fisheries as a source of protein. After the introduction of gill nets in Lake Victoria in 1905, catches of the endemic fish species gradually declined due to increased fishing effort, as observed for the period 1905–1928.

A further increase of fishing effort during the 1940s with the use of illegal undersized, mesh sizes and the introduction of nylon nets and outboard motors in the 1950s resulted in overfishing and a sharp reduction in the catches in the inshore areas.

The high demand for fish led to the introduction of exotic species into Lake Victoria. The tilapias *Oreochromis niloticus*, *O. leucostictus*, *Tilapia zillii*, and *T. remdalli* (“*melanopleaura*”) were introduced during the 1950s and 1960s and eventually replaced the indigenous species. The Nile perch found his way into the Lake in the early 1950s, by unofficial and official means, before the results of a pilot experiment carried out in Lake Kyoga in the 1950s to determine the advisability of stocking the Lake with fish were available. Recent research revealed that the Nile perch from Lake Victoria differs taxonomically from lake species collected elsewhere, including *L. niloticus rudolfianus*, *L. niloticus longispinus*, *L. albertianus*, *L. marcrophthalmus*, and *L. niloticus niloticus*.

The introduced species resulted in increased commercial catches. In 1989, the lake produced over 500,000 t of fish, predominantly Nile perch (63%), dagaa (*Rastrineobola argentea*) (19%), and Nile tilapia (9%). Provisional estimates for the years 1990 and 1991, as official data are not yet available, would indicated that catches have been leveling off. The ecosystem is still largely unstable and the level at which the fish production of the lake will stabilize is simple not predictable. The management of the Nile perch fishery is therefore seen as an utmost priority. Predation by Nile perch and competition with introduced tilapias have caused a severe decline, and in some cases total disappearance, of native species.

Fish has always been an important source of food for people around the lake. The increased production of table fish from 44,000 to 405,000 t between 1975 and 1989 must have had a significant impact on the food availability around the lake basin and also to more distant urban centers in the three countries. The presence of Nile perch drastically changed the nature of fishing operations, fish processing, and marketing. The total value of production at market level has been estimated at US\$ 270 million for 1989. In Kenya and Tanzania the value of production increased by 500% and 750%, respectively, between 1985 and 1990 (Figures 1 and 2).

In August 1992, a Workshop on “People, Fisheries, Biodiversity and the Future of Lake Victoria” was held in Jinja. Summarizing current and recent research of limnology, ecology, and socioeconomics of the lake and its catchment in some 50 presentations, scientists from Uganda, Kenya, Tanzania, Europe, Israel, Canada, and the USA concluded that the limnology and environment of Lake Victoria are undergoing rapid change and that this will have serious implications for the fisheries of the Lake and result in a deterioration of the social and economic welfare of its riparian population. Resolutions in this workshop underscored the urgent need for understanding current changes in limnology of the lake and include

Victoria Lake, Figure 1 Eastern Africa showing the Rift Valleys and their lakes. Lake Victoria lies between the two rifts.

Victoria Lake, Figure 2 Topographic map of the catchment area of Lake Victoria.

the development of a general ecosystem model, the improvement of the understanding of the controls on oxygen distribution and levels of food web alterations, its effects on water quality and lake productivity, and the determination of the energy flows of the two major trophic detritus. Furthermore, it was recommended that research and management programmed for the fringing wetland and forest habitat should be undertaken and that special attention should be given to the explosive growth of the water hyacinth in the lake.

Research on the pollution of the lake and its catchment has become increasingly important in recent years. Pollution studies in Kenya have been carried out by the university of Nairobi and KMFRI. Recent hydrological research on Lake Victoria has mainly focused on the assessment of the different components of the water balance in order to predict changes in water level and the flow of the Nile.

Lake Victoria is a shared water body. Resources use by one of the riparian countries impacts the activities of the other countries. Regional cooperation in environmental

management of the lake basin is being envisaged with the assistance of UNEP and the World Bank in order to harmonize management objectives and to provide a framework within which to resolve user conflicts and transboundary issues.

Management of water availability, water quality, and lake pollution is only possible with an improved scientific understanding of the limnology and hydrology of the lake and of the effect of anthropogenic activities on the lake environment. This requires regional collaboration and coordination of limnological and hydrological research.

Emil Pasha, a German doctor, was a naturalist and ornithologist. During the 12-year stay on the Nile north of Jinja, he sent out thousands of birds and animals and thousands of specimen of plants of the region to museums in Europe. He also made records of rainfall and geology of the country. In 1890, on his way to his camp near Lake Albert, he founded the town of Bukoba on the western shore of Lake Victoria. Upon his return to the shore of Lake Albert he found his camp in total disorder. He went

on into the Congo, where he was killed in 1892 by a group of Arab slavers. He was the first pioneer naturalist combining the pure geographical exploration and scientific research in the fields of biology, geology, medicine, and anthropology. At this time, when most of the geographical problems had been solved, European scientists were becoming interested in the exciting new, virgin area of tropical Africa. The first scientific expeditions in the region were those of J.W. Gregory, a Scottish geologist who worked in the East African Rift Valley and J.E.S. Moore's expeditions to Lake Tanganyika in 1894 and 1897, which can be regarded as the foundation of tropical African limnology.

Hydrological research

Limnological investigations of Lake Victoria and other East African lakes evolved from rather short-term investigations in the beginning of the century mainly focused on collecting specimens and carrying out simple physical measurements, to more extended physical and chemical measurements, and finally to the foundation of research institutes on the shores of the lakes which permitted prolonged investigations and the use of research vessels.

Regular measurements of water level have been recorded since 1902 at Kisumu and the first bathymetric survey of the lake was completed in 1900. Stuhlmann, the zoologist who accompanied Emin Pasha on his trip to Lake Albert in 1890, was in 1892 the first collector of Algae from Lake Victoria at Bukoba and later several others followed.

Before the Second World War the first and only systematic biological research on Lake Victoria was the Fishing Survey of Lake Victoria in 1927–1928 by Micheal Graham. In appendix 3 of the report the physiography of Lake Victoria is described with information on geography, geology, the climate of the region, and some physical and chemical characteristics of the lake, and in Appendix 8 an outline of the ecology of Lake Victoria is given. Limnological observations on physical characteristics and a study on zooplankton of Lake Victoria were carried out during the Fishing Survey if 1927–1928 by Worthington.

After the Second World War newly founded research institutes and universities in the three territories around the lake (Uganda, Kenya, and Tanganyika) became increasingly important for hydrological and limnological research on the lake.

In 1947 the East African fisheries Research Organization (EAFRO) (later the East African Fresh Water Fisheries Research Organization) (EAFFRO) and presently the Uganda Freshwater Fisheries Research Institute (UFFRO) at Jinja (Uganda), was the first research organization established under the East Africa High commission and focused on Inland fisheries in East Africa. This organization, with R.S.A. Beauchamp as its first director, advanced to a large extent the knowledge of Lake Victoria and other East African inland waters and their fisheries. In 1975 substations of EAFFRO were established in

Kisumu (Kenya) and Mwanza (Tanzania). The station at Kisumu (Kenya) is now the Kisumu laboratory of the Kenya Marine and Fisheries Research institute (KMFRI). In Tanzania the substation first was renamed the Freshwater Fisheries Research Institute (FFRI). Presently it is a substation on the Tanzanian Fisheries Research Institute (TAFIRI).

In 1949 another organization was established under the East Africa High Commission with its headquarters in Kisumu (Kenya), the Lake Victoria Fisheries Service (LVFS). It became responsible for fishery production and management in the lake and had vessels based in Entebbe, Kisumu, and Mwanza.

The only major center for higher education at the time was Makerere College at Kampala, which was to become the first university in East Africa. Several departments of the university became involved in lake research. In Kenya, departments of the University of Nairobi, the second university in the region, were involved in hydrological and limnological research in the Kenyan waters of Lake Victoria, predominantly of the Nyanza Gulf. In Tanzania, the Tanzania fisheries Research Institute (TAFIRI) and departments of the third university in the region, the University of Dar-es-Salaam, have been responsible for limnological research on the lake. Finally, the Fisheries departments of the three countries, although mainly involved in fisheries, have carried out studies.

An important contribution to the limnology of Lake Victoria and African limnology in general has been made by the Freshwater Biological Association (FBA) of the UK, starting with R.S.A. Beauchamp the first director of EAFRO, who spent several years on the lake and the first director of the FBA, E.B. Worthington, who was already working on the lake in 1927. Past and present members of FBA have been engaged in limnological research on Lake Victoria. The Lake has been subject to several hydrological investigations of which the latest is the Hydromet Survey, a cooperative venture between the Nile Basin countries (Burundi, Egypt, Kenya, Rwanda, Sudan, Tanzania, Uganda, and Zaire with Ethiopia as observer), the United Nations Development Programme (UNDP), and the World Meteorological Organization (WMO).

Recent limnological research on Lake Victoria has been carried out by the local research institutes in cooperation with research institutes and universities in Europe and North America, and occasionally Japan, and international organizations such as FAO and UNESCO. Of all inshore waters, the bays near Jinja have the longest record of limnological research having been studied since the late 1940s when EAFRO was founded. Nyanza Gulf has been intensively studied during the last two decades. Research recently has been focused especially on the relations among fish kills, algal blooms, and eutrophication. Limnological studies in the Mwanza Gulf started in 1973 and were carried out continuously from 1978 by the HEST/TAFIRI project, although limnological monitoring was more or less limited to those parameters relevant to fish ecology and fisheries. The largest part of the lake, with offshore waters deeper than

60 m, was first studied in 1927–1928. Recently, limnological research on a number of offshore sampling stations, including underwater observations with operated vehicle (ROV), have been carried out as part of the eutrophication research projects in Uganda and Kenya.

Over the last 25 years a growing number of African limnologists have contributed to the limnology of Lake Victoria and other East African lakes, resulting in an increasing number of scientific publications on the subject.

History

The first scientific research on Lake Victoria goes back to the expeditions to find the sources of the Nile, which constituted the first hydrological research on Lake Victoria. A compelling book on the explorers and conquerors of the sources of the Nile was written by Moorehead and has been used as the main reference for the following short historical overview.

The European discovery of Lake Victoria was made by two German missionaries, Johann Krapf and Johann Rebmann, from a missionary post in Rabai near Mombasa. They were the first Europeans to see the mountains of Kilimanjaro (1848) and Kenya (1849), respectively. In 1855 they produced, together, with another missionary, J.J. Erhardt, a map showing a large inland lake called “Unyamwezi Sea.” At the same time there were local reports from Arab slave and ivory traders of two large lakes “Jimi” and “Nyanza” and a third lake “Nyasa” further south. The Royal Geographical Society in London became interested and supported an expedition by Richard Burton and John Hanning Speke to investigate the reports of the lakes and their relation to the River Nile.

They decided to start from Zanzibar and approached the lakes from the East African coast, and with this expedition the period of the Central African exploration began. In 1858 they first discovered “Ujiji,” the present Lake Tanganyika. During the expedition they heard about another lake further north and John Speke left Burton in Kazeh, now called Tabora (Tanzania), and reached the southeast end of the second large lake, which he named after Queen Victoria (the Gulf that he discovered was later named after him). In 1862 John Speke and James Grant found the outlet of Lake Victoria near Jinja. Later in 1875 Stanley circumnavigated Lake Victoria by canoe in two months (the first lakewide survey) and confirmed Speke’s hypothesis that it was one great lake with a single outlet at Ripon Falls (near Jinja). He started his trip near Mwanza, sailed directly to Ripon Falls along the east side of the lake, and returned along the west side to Mwanza. In the years following that trip other expeditions were made to or passed through the lake. In 1884 the Scottish explorer Joseph Thompson made a journey through Masailand and reached the northeastern shore of Lake Victoria east of Ripon Falls. In 1889 Stanley and Emin Pasha (Eduard Schnitzer) returned from the latter’s camp near Lake Albert along the southwest shore of Lake Victoria via Kazeh to Bagamoyo on the East African coast near Zanzibar.

With these explorers of the 1800s began the period of exploration of Central African lakes.

Appendix: Hydrology

Inflow 18.10^9 m^3
 Precipitation 100.10^9 m^3
 Outflow 23.10^9 m^3
 Evaporation 100.10^9 m^3
 Annual lake level fluctuations 0.4–0.7 m
 Maximum lake level fluctuation 3 m
 Flushing time 140 years
 Residence time 23 years
 Area $68,800 \text{ km}^2$
 Volume $3,200 \text{ km}^3$

VOLUME OF WATER IN LAKES AND RESERVOIRS: DETERMINATION

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Introduction

There are basically two methods of determining the volume, capacity, or storage of lakes and reservoirs:

1. Conventional surveying method
2. Electronic distance measurement (EDM) using the Global Positioning System (GPS) Total Station method

In both cases the objective is to establish a relation between water level and volume.

Volume determined by conventional surveying methods

This method, although now seldom used for the estimation of volume, requires a launch equipped with echo sounder, the position of the launch on the lake being fixed by sextant or theodolite. The soundings of depth are taken along carefully selected cross sections.

The positioning of the cross sections takes account of the size and shape of the lake or reservoir but is not usually more than 1 km apart, the general rule being that the volume between cross sections is representative of the volume of the valley between ranges. For best results, the selection of cross sections is similar to that in the selection of verticals in streamflow measurement so that the volumes of each segment (the volume between cross sections) should not be more than a specified percentage of the total volume. Targets, in accordance with ISO 4366, are located at both ends of each section to maintain the launch on the section line.

Contours are plotted using all measured values of soundings on the cross sections, both below and above the water surface. The scale of the plot depends on the size and area of the lake or reservoir and may be to a scale of between 1:200 and 1:20,000 with a vertical scale of about 20–30 cm (see Figures 1 and 2 and Table 1).

The total volume is estimated by the use of the prismoidal end area or other method using the area enclosed by each contour with a constant vertical interval between each contour.

If staff or reference water level gauges are available, these are read at suitable intervals during the survey.

As stated above, the method is seldom used today especially if the surface area of the lake or reservoir is

greater than, say, 500 km² and whose linear dimensions are more than 10 km. It should be noted, however, that Sir John Murray's bathymetric survey of 562 Scottish lochs during the period 1897–1909 used this method albeit using equipment only available at that time.

Bathymetric maps

For example, a bathymetric map can be generated by appropriate software in conjunction with EDM or GPS equipment. See Figures 1 and 2 and Table 1.

Volume estimated by modern surveying methods

The introduction of a fully integrated survey system uses a combination of theodolite, EDM instrumentation, data processor, and dedicated software giving x, y, and z coordinates directly and encompassing everything from field observations to the production of the final plans. The system is known as the Total Station.

All survey data are transferred from the Total Station to an electronic notepad allowing input in three-dimensional coordinates.

The system, apart from speed and accuracy, allows the largest of lakes and reservoirs to be surveyed, the maximum range of an EDM Total Station being about 8 km.

The system is based on measuring the transit time of an electromagnetic beam emitted from a transmitter-receiver to a reflecting target and back.

A combination of EDM and theodolite allows the electromagnetic beam to pass through the telescope optical system. The prisms are carefully located round the lake or reservoir with respect to the EDM Total Station and the launch position. These modern techniques no longer require the tedium of working along cross sections.

Annual area-specific loss (m ³ /km ² /year)	← 362.66 →					

The GPS receiver

Twenty-four GPS satellites (see "Appendix") orbit the earth twice per day at an altitude of 20,200 km. Receivers on the ground calculate their positions by making distance measurements to four or more satellites. These satellites function as reference points which broadcast satellite identity, position, and time information by a carrier frequency of 1575.42 MHz in the UHF band. Measurements of distance to each individual satellite are made by analyzing the time taken for a signal to travel from a satellite to a GPS receiver. Trilateration is then used to establish the GPS receiver's position, and since latitude and longitude and height of each point are displayed, distances between points are also displayed.

The GPS system of surveying

A receiver on the launch displays position and sounder data. With such a receiver in the traveling mode, the GPS Total Station can troll the lake or reservoir without the necessity of defining range locations. One base station set up can serve many roving unit outstations equipped with receivers and data links within a 10-km radius. There is, therefore, no practical limit to the size of the lake or reservoir to be surveyed; it only depends on the number of base stations and rovers which can be set up.

The survey can be extended by mounting the GPS Total Station on a vehicle and provide contour and topographic information. For small water bodies, a combination of vehicles and surveyors with backpacks can be employed. Each GPS receiver, whether tripod mounted, vehicle mounted, rover, or backpack, accepts and processes raw distance signals from multiple GPS satellites. All GPS data and sonar data are transferred directly from handheld survey controllers and converted by dedicated commercially available software packages into the necessary output of bathymetric maps, contour plans, lake or reservoir configuration, three-dimensional drawings, and water level volume curves.

The rover unit merges carrier phase data broadcast from the base station with incoming satellite signals to establish three-dimensional coordinates of the survey points with an accuracy of 10 mm.

Water level measurement

The water level is measured according to ISO 4373. The number of water level measuring stations depends on the size and shape of the lake or reservoir. The objective is to ensure that the measured values are sufficient to establish the mean horizontal water level and the volume of live, total, or flood storage.

To determine the number of stations necessary, consideration is given to any wind setup, surface curvature, outflows and inflows, seiches, and long-wavelength waves.

The following table is given as a guide (Table 2):

Volume of Water in Lakes and Reservoirs: Determination, Table 2 Guide to determine the number of necessary stations

Surface area km ²	10,000	5,000	1,000	500	<500
Number of water level stations	6–8	4–6	2–4	2	1

For small reservoirs (<500 km²), the location of a reference or staff gauge at the draw-off tower is common practice especially if a relation can be established between the gauge and average water level.

Acknowledgement is made to the International Standards Organization, Geneva, for permission to reproduce Figures 1 and 2 and Table 1 at www.iso.org.

Appendix

The GPS satellite system

The Global Positioning System (GPS) is a satellite-based navigation system made up of a network of 24 satellites placed into orbit by the US Department of Defense. GPS was originally intended for military application, but in the 1980s the U.S. government made the system available for civilian use. The GPS works in any weather conditions anywhere in the world 24 h a day. There are no subscription fees or setup charges.

The GPS satellites circle the earth twice a day in a precise orbit and transmit signal information to earth. GPS receivers take this information and use triangulation to calculate the user's exact position.

Essentially, the GPS receiver compares the time a signal was transmitted by a satellite with the time it was received. The time difference tells the GPS receiver how far away the satellite is. With distance measurements from a few more satellites, the receiver can determine the user's position and display it on the unit's electronic map.

A GPS receiver must be locked on to the signal of at least three satellites to calculate a 2D position (latitude and longitude) and track movement. With four or more satellites in view, the receiver can determine the user's 3D position (latitude, longitude, and altitude). Once the user's position has been determined, the GPS unit can calculate other information such as speed, bearing, track, trip distance, distance to destination, sunrise and sunset time, etc.

The GPS receivers are extremely accurate and three to five meters are common.

The 24 satellites that make up the GPS space segment are orbiting the earth about 12,000 miles (19,000 km) above the earth making two complete orbits in less than 24 h. The satellites travel at speeds of 7,000 miles/h (11,000 km/h). They are powered by solar energy having backup batteries onboard to keep them running in the event of a solar eclipse when there is no solar power. Small rocket boosters on each satellite keep it orbiting in the correct path.

Synonyms

Estonian name: Võrtsjärv; English name: Lake Võrtsjärv;
 Russian name: Озеро Вуртсъярв
 Historical name forms: Werzjerw See; Wirtsjerw See; See Wirzjerw; Озеро Вирцерв

Location and catchment geography

Lake Võrtsjärv, the second largest lake in the Baltic countries, is located in a shallow preglacial basin in the southern part of Estonia, centered around 58°17'N and 26°03'E (Figure 1). At mean water level, the lake area is 270 km², volume 750 millions m³, mean depth 2.8 m, and maximum depth 6 m. The deep site located close to the eastern shore in the southern part of the lake is confined to a small area where sediment accumulation is prevented by strong compensating currents occurring at most wind directions (Kivimaa et al., 1998). The meridionally oriented axial length of the lake is 34.8 km and the maximum width 13.3 km. The coasts are generally low except at the eastern side where Devonian sandstones are exposed in places as steep banks. There are 4–5 small moraine islands in the southern part of the lake.

From the 3,374-km² drainage basin (including the lake itself), 3,275 km² is located in Estonia and 99 km² in Latvia. The basin is conventionally bordered by the 40-m isohypse, while the altitude of the lake surface is 33.63 m at the long-term mean water level. Major part of the drainage basin (53%) is covered by forest, agricultural lands make up 33%, water bodies 9% (mainly the lake itself), and wetlands 3% of its total area (Figure 2). The outflowing Emajõgi River connects the drainage basin to the watershed of Lake Peipsi (47,800 km²). Among the 154 rivers and streams within the Võrtsjärv catchment, only 40 have a length over 10 km. The longest is the Õhne River (94 km) and the largest the Väike Emajõgi River, which basin occupies 40.9% of the total catchment area (Figure 1).

Since 2006, the whole lake and parts of its shore ecosystems are included in Võrtsjärv limited conservation area, which largely overlaps with the Võrtsjärv Site of Community Importance and Võrtsjärv Special Protection Area under Natura 2000.

Geology of the lake basin and bottom deposits

The Võrtsjärv depression in the Middle Devonian baserock is of preglacial origin but has been strongly influenced by deglaciation processes and tectonic movements. According to Moora and Raukas (2004), after the retreat of the ice from southern Estonia began some 13,000 ¹⁴C years ago, first, a narrow fluvial body of water, so-called Small Võrtsjärv, formed that developed into a larger Ice Võrtsjärv, which water level was controlled by the Peipsi ice-dammed lake. The stage of the Ancient Võrtsjärv started from the final lowering of the water level and development of an outflow into the Baltic Ice Lake around 12,000 years ago. The beginning of the Holocene marks the boundary between Ancient Võrtsjärv and Big Võrtsjärv, a transgressive body of water of considerably larger area than the present lake. The stage of Contemporary Võrtsjärv started when the outflow to the west finally closed and the outflow to the east via the Emajõgi Valley opened some 7,500 years ago, lowering the lake level. Presently, due to an uneven neotectonic land uplift, Lake Võrtsjärv is retreating southward, inundating new areas (Miidel et al., 2004).

Varved clays accumulated in Ice Võrtsjärv and sand and silt in Ancient Võrtsjärv (Moora et al., 2002). Lake marl accumulation started in the Big Võrtsjärv stage in the Early Holocene (Miidel et al., 2004). Biogenic sedimentation, coastal erosion, and transport of suspended solids by rivers are the principal sources of material for the bottom deposits of Võrtsjärv. About two thirds of the lake bottom is covered with mud lying on marl, and the thickness of these layers increases toward the south reaching 7 and 4.7 m, respectively (Veber, 1973). Varved clays lying under marl are exposed in the form of a sandy, muddy-sandy, or clayey bottom, mostly in the northern part of the lake.

Hydrology

According to the annual mean water balance of the lake for the period 1961–2000 (Järvet, 2004), 83% of the lake's water income was accounted for by the inflow from rivers and 17% by direct precipitation on the lake surface. The water losses partitioned in nearly similar proportions (84% and 16%, correspondingly) between the outflow and evaporation. The components of the balance have a clear seasonal dynamics with the highest income during the spring flood peak and the highest outflow and evaporation during summer (Figure 3). The average water retention time is one year. During higher water periods, on average 16 days per year, reverse flow may occur in the upper course of the River Emajõgi, leaving the lake without outflow (Järvet, 2004).

The long-term (1922–2003) mean water level of Võrtsjärv is 33.63 m above sea level. In September 1996, the water level dropped to 32.20 m, the lowest value ever recorded in Võrtsjärv, and the highest water level (35.28 m) was measured in November 1923 (Järvet, 2004).

Võrtsjärv Lake in Estonia, Figure 1 Location map of Võrtsjärv and the main sub-basins of the catchment. (Modified from Järvet et al. 2004.)

The absolute water level range of 3.1 m exceeds the mean depth of the lake and corresponds to a 1.4-fold (89 km^2) difference in the lake area, 2.4-fold (2.2 m) difference in the mean depth, and 3.3-fold ($845 \times 10^6 \text{ m}^3$) difference in the lake volume (Table 1). Large seasonal and annual fluctuations of the water level are one of the most characteristic features of Võrtsjärv. Because of the restricted outflow, it takes the entire summer for the flood water to leave the lake, whereas the height of the flood peak in spring strongly determines the annual mean water levels

($R^2 = 0.85$, $p < 0.0001$, Järvet, 2004). The annual mean amplitude of the water level is 1.4 m.

Nearly coincident periodicities in annual water levels and the North Atlantic Oscillation index for winter (NAOw) can be found for several large lakes in north-eastern Europe (Figure 4). In Võrtsjärv, NAOw was negatively correlated with the end of the ice cover and positively with the lake's mean depth in spring. The influence of NAOw on water levels is likely achieved through the variable amount of precipitation (Nõges et al., 2010a).

Vörtsjärv Lake in Estonia, Figure 3 Mean monthly water balance of Lake Vörtsjärv for the period from 1961 to 2000. The loss components of the balance are marked as *negative*. (Data from Järvet 2004.)

Vörtsjärv is polymictic. Water temperature reaches its maximum usually in the second half of July or at the beginning of August. The annual maximum surface water temperature has varied from 20.4°C to 27.5°C with a long-term average of 23°C for the period 1947–2000 (Järvet, 2004). Based on daily data for the ice-free periods of 1961–2004, there has been a highly significant

Water level, m a.s.l.	Date, period	Mean depth, m	Area, km ²	Volume, 10 ⁶ m ³
35.28 – abs. maximum	26.11.1923	3.71	327	1,214
33.63 – long term average	1922–2003	2.79	270	750
32.20 – abs. minimum	06.09.1996	1.55	238	369

Vörtsjärv Lake in Estonia, Figure 4 Spatial coherence in annual mean water level of three large lakes in north-eastern Europe. Water level data for Lake Vörtsjärv (Estonia) and Lake Peipsi (Estonia/Russia) were obtained from the Estonian Institute for Meteorology and Hydrology (Data for Lake Ladoga (Russia) were taken from Jaani (1973). All series were smoothed with a 7-year moving average. The time series of the North Atlantic Oscillation index (Hurrell et al., 2001) is shown for comparison).

($p < 0.01$) temperature increase of 0.42°C per decade in August (Nõges, 2009).

The annual ice cover lasts on average for 131 days (minimum 55, maximum 168 days in 1923–2003) from mid-November until mid-April (Järvet, 2004). The maximum ice thickness has varied from 26 to 98 cm with a mean value of 52 cm.

Underwater light conditions

The diffuse attenuation coefficient $K_{d,PAR}$ ranges typically from 1.54 to 2.95 m⁻¹ in Vörtsjärv, resulting in 5–20-fold attenuation of photosynthetically active radiation (PAR) by one meter layer of water. The euphotic depth, estimated as the penetration depth of 1% of the subsurface PAR, varies from 1.6 to 3.2 m, most covering the 2.8-m water column. In Vörtsjärv, pure water absorbs 7–11% of PAR, phytoplankton pigments 11–20%, and scattering accounts for 19–25%, while humic substances may absorb 40–52% of total PAR. From January to March, snow cover causes 40–60% of the losses of incident light, while the

light attenuation by ice varies from 4% in December to about 26% in March (Reinart and Nõges, 2004).

Water and sediment chemistry

Waters collected by the tributaries from the surrounding moraine uplands have an alkalinity around 200 mg l^{-1} (Table 2) and are dominated by hydrocarbonate and calcium ions. The alkalinity and conductivity of water are highest in winter and decrease by about 20% in summer due to phytoplankton activity. The water is well buffered, and the mean pH ranges from 7.9 in winter to 8.5 in summer. The state monitoring data (1994–2009) show significant upward trends in alkalinity for spring and summer and in pH for summer, autumn, and winter. A rapid increase in sulfate and chloride concentrations from the 1950s to the 1980s was followed by a decrease in the following decades. The continuous decrease in the chloride concentration from 18 in 1989 to 7 mg l^{-1} in 2001 is the most striking change among the major ions. The most probable reason for this is the disintegration of large collective farms and the construction of wastewater treatment facilities (Tuvikene et al., 2004). Suspended solids concentration has a remarkable seasonal variation due to strong sediment resuspension and abundant phytoplankton during the ice-free period.

Võrtsjärv is highly eutrophic, characterized by mean annual total nitrogen (TN) concentration of 1.4 mg l^{-1} and total phosphorus (TP) concentration of $50 \text{ } \mu\text{g l}^{-1}$ (Table 2).

The riverine nutrient loading into Võrtsjärv increased rapidly in the 1980s followed by a decrease in the early 1990s caused by declining agricultural land use intensity in Estonia (Liira et al., 2008). For the period 1992–2007, TP concentrations in the main inflow of Võrtsjärv showed a highly significant decreasing trend (Nõges et al., 2010a)

reflected also in total loadings (Figure 5). TN loadings, which declined rapidly during the 1990, have slightly gone up again in the 2000s, whereas the drop in TP loadings continued.

The state monitoring data (1994–2009) revealed significant ($p < 0.05$) decreasing trends in in-lake TP concentrations for spring and summer with corresponding rates of -0.7 and $-1.8 \text{ mg m}^{-3} \text{ year}^{-1}$, and in nitrate nitrogen concentration for summer. The strongest trends among the analyzed chemical variables were found in permanganate oxygen demand (COD_{Mn}), which increased with a rate of $0.26\text{--}0.32 \text{ mg O l}^{-1} \text{ year}^{-1}$ for all seasons. As biochemical oxygen demand was rather decreasing, the change in COD_{Mn} can likely be attributed to an increase in the concentration of humic substances. Dissolved oxygen concentrations increased highly significantly for winter over the 16-year period, obviously due to more frequent mild winters in the later years. Secchi depth declined highly significantly for winter and summer, which could be caused by the increase in both humic substances and chlorophyll *a* (Chl-*a*) concentrations.

Erosion bottoms with predominantly coarse materials, such as sand and gravelly sand, predominate in the northern part of the lake. Southward, a smooth transition over silty sand, sandy silt, silt, silty clay, and sapropelic silty clay to gyttja (Raukas, 1995) marks the trajectory of sediment focusing in the lake. Wind and wave action accounts for 87% of the observed spatial variability of sediment dry weight in Võrtsjärv (Nõges and Kisand, 1999b).

In the upper 0–2-cm sediment surface layer, sediment dry weight (DW) remains mostly below 10% of the wet weight (WW) but may reach as high as 60% in the erosion area. The organic matter content is around 20% of DW, on average, but varies from less than 5% of DW to more than 35%. Accumulation of lighter sediments to more sheltered

Võrtsjärv Lake in Estonia, Figure 5 Long-term dynamics of nitrogen (a) and phosphorus loading (b) to Võrtsjärv.

bottom areas is reflected also in the horizontal distribution of sediment phosphorus forms which correlate strongly (R^2 from 0.72 to 0.96) with the dry matter content of the surficial sediment (Nõges and Kisand, 1999b). Phosphate release from the sediment is usually prevented by high Fe/P ratio (26:30) and the aeration of the sediment surface by frequent resuspension, that keeps phosphate adsorbed and maintains a low concentration of soluble reactive phosphorus in pore water (typically $<10 \mu\text{g l}^{-1}$). At low water levels, however, severe storms can entrain substantial quantities of the deeper, anoxic sediments, releasing occasionally large amounts of phosphorus (Nõges and Kisand, 1999a).

Budgets of substances

Võrtsjärv acts as an efficient trap for nutrients, which accumulates more than a half of the external N load and about one third of the external P load during the annual cycle. The nitrogen loss is mostly accounted for by denitrification while phosphorus is buried in the sediment. Seasonal and inter-annual variations in the water level have a major effect

on the annual nutrient budget of the lake. A comparison drawn between 2 years, 1990 and 1995 (Nõges et al., 1998), showed clearly how the retention of nutrients was regulated by the combined effects of rainfall and water level fluctuations. In low-water years, the external P loading to the lake is smaller; however, resuspension becomes stronger and more phosphorus is released from the sediment. Also, the loading of TN is smaller in low-water years, but unlike phosphorus, nitrogen losses are strongly enhanced by resuspension that brings nitrates into contact with anoxic sediment layers, the site for denitrification. As a result, most of nitrogen is released to the atmosphere.

Examination of a 28-year record found that both water color and COD_{Mn} were positively related to discharge throughout the year, with significant correlations in the months of March and June and from August to November (Nõges et al., 2007). In addition, water color and COD_{Mn} in spring were positively related to the NAOw index of the previous winter, reflecting the occurrence of increased precipitation in high NAO years. A recent study (Pall et al., 2011) showed that the lake retained nutrients

(N, P, and Si) irrespective of whether the water retention was positive or negative, but the balance between accumulation and emission of total organic carbon (TOC) and dissolved inorganic (DIC) and organic carbon (DOC) depended strictly on lake's water budget.

Biota

Phytoplankton

Primary production (PP) of phytoplankton in Võrtsjärv has been measured in situ with ^{14}C -assimilation technique in 18 years during the period from 1982 to 2009. The full time series was reconstructed, using a semi-empirical PP simulation model (Arst et al., 2008) based on continuously measured PAR irradiance and interpolated values of monthly measured Chl-a. According to the long-term annual PP ($208 \pm 27 \text{ gC m}^{-2} \text{ year}^{-1}$), Võrtsjärv is close to the global nutrient-saturated production boundary for lakes determined by latitude where light limitation has the leading role (Nöges et al., 2011). This assignment is supported by the composition of phytoplankton dominated by eutrophic and highly shade tolerant cyanobacteria from the genus *Limnothrix*.

Although more than 500 taxa of algae have been identified in phytoplankton, phytobenthos, and periphyton of Võrtsjärv (Pork and Kõvask, 1973), the phytoplankton of the lake can be considered species-poor, and usually, two to three species form the bulk of the biomass. Cyanobacteria and diatoms dominate overwhelmingly, while all other groups of algae together commonly build up less than 10% of the biomass. Among these minority groups, chlorophytes, cryptophytes, dinophytes, and chrysophytes are more abundant, whereas euglenophytes and xanthophytes are rare.

Among cyanobacteria, two filamentous species, *Limnothrix planktonica* (Wolosz.) Meffert and *L. redekei* (van Goor) Meffert, are the most numerous, occurring in plankton all year round. These species are accompanied by two other filamentous cyanobacteria, *Planktolyngbya limnetica* (Lemm.) Kom.-Legn. and *Aphanizomenon skujae* Kom.-Legn. & Cronb. The diatoms are dominated by long cylindrical *Aulacoseira* species and needle-shaped species of *Synedra*. Because of strong wave action, benthic and periphytic diatoms from genera *Surirella*, *Gyrosigma*, *Nitzschia*, and others become detached from the substrate and occur frequently in phytoplankton. Only in spring, spherical, ellipsoidal, or disk-shaped algae from different taxonomic groups may become temporarily dominating. A study carried out in Võrtsjärv from August to December 1997 showed the important role of autotrophic picoplankton ($<3 \mu\text{m}$), which formed on average 14% of the total phytoplankton biomass and contributed 30–70% to the total PP for this period (Nöges et al., 2004).

Seasonally, the control of phytoplankton growth is mediated by ice conditions in spring and by water level in summer and autumn (Nöges et al., 2010a). Large year-to-year differences in the water level have a pronounced effect on the development of the phytoplankton.

Since 1964, the phytoplankton biomass has been significantly lower in years of high water level, a pattern that was not related to any change in external loading of nutrients (Nöges et al., 2010b). Besides the largely variable nutrient loadings, fluctuating water levels have had a particular role in the succession of dominating species. A study of the 44-year data series on Võrtsjärv phytoplankton (Nöges et al., 2010c) suggests a non-linear response of phytoplankton to changing nutrient loadings and the occurrence of a regime shift between 1977 and 1979 triggered by an abrupt water level increase, which supported the establishment of the new highly shade tolerant phytoplankton community dominated by *Limnothrix redekei* and *L. planktonica*. Low-water periods are often characterized by an increase in the nitrogen-fixing species, *Aphanizomenon skujae*. Nitrogen fixation, recurrently measured in Võrtsjärv in summers with low water levels, has likely been triggered by increased nitrogen losses due to denitrification (Tönno and Nöges, 2003).

Macrophytes

Despite its shallowness, Võrtsjärv is not a macrophyte-dominated lake, and the area colonized by macrophytes is less than 25% of the total lake area (Table 4). A large diversity of habitats supports a great variety of different species including, besides real aquatic plants, several species of wetland and swamp vegetation. Over time, a total number of 114 species have been described in the lake (Mäemets, 2002).

The littoral zone of Võrtsjärv has a very gentle slope. The average width of an up to 1 m deep zone is 250 m, varying from 50 to 700 m. The littoral zone is covered by a wide belt of aquatic macrophytes, dominated by *Phragmites australis* (Cavan) Trin. ex Steud. (common reed) and some other helophytes such as *Schoenoplectus lacustris* L. Palla (common club rush) and *Typha angustifolia* L. (narrow leaf cattail), and is frequently bordered by the nymphaeid *Nuphar lutea* L. Sm. (yellow water lily) (Feldmann and Nöges, 2007). The stands of helophytic vegetation are quite dense, the average number of stems ranging from 14 to 23 m^{-2} for reed, 30–37 m^{-2} for club rush, and 13–14 m^{-2} for cattail (Liira et al., 2010).

The macrophyte vegetation of the lake has a strongly polarized character. The wind-exposed northern and eastern coasts are bordered by a species-poor, partly fragmentary reed belt, while the southern corner of the lake is fully overgrown with vegetation. In this part of the lake, all vegetation zones are abundantly represented. The vegetation along the more wind-protected western coast is richer compared to the eastern coast and has a denser and wider helophyte zone bordered in places by *N. lutea* and a continuous belt of well-established submerged vegetation. The polarized character of macrophyte distribution in the lake resulting from the particular combination of the dominating wind direction, the shape of the lake basin, and the irregular distribution of the inflows (Feldmann and Nöges, 2007) were noticed already by the Baltic German botanist Klinge (1890) who formulated his rule on

the impact of dominating wind direction on overgrowing of lakes.

A retrospective analysis of satellite images (Liira et al., 2010) for the period 1985–2007 showed that the helophytic macrophyte belt, dominated by *P. australis*, has rapidly widened during the last two decades, with an average expansion rate of 2.2 m year^{-1} , which was amplified 1.6 times the vicinity of large inflows. Expansion of reeds and decline of several submerged and shallow-water species in response to eutrophication are typical changes observed as well in Lake Peipsi, the largest lake in the Baltic states (Mäemets, 2002).

According to ^{14}C measurements in the littoral area in summer, the dominant submerged macrophytes, *Potamogeton perfoliatus* L. and *Myriophyllum spicatum* L., contributed 58%, their epiphytes 0.1%, and littoral phytoplankton 41.9% of the $12.0 \text{ g C m}^{-2} \text{ day}^{-1}$ total PP of the submerged macrophyte area. The littoral area contributed 35.5% to the total PP of the lake in summer (Nõges et al., 2010b).

Bacterioplankton

In 1963–2001, the total number of bacteria varied from 0.28–11 (average 3.7) mln cells ml^{-1} , reaching a maximum in the mid 1970s and a minimum in the mid 1990s (Tammert and Kisand, 2004), and has been increasing since then (Estonian State Monitoring, 2011). The bacterial biomass (BB) is low under the ice ($<75 \text{ mg C m}^{-3}$) and varies during the rest of the season from 100 to 500 mg C m^{-3} with the highest values from July to September. Bacterial production (BP) is generally low from November to February ($<150 \text{ mg C m}^{-2} \text{ day}^{-1}$) and high ($300\text{--}700 \text{ mg C m}^{-2} \text{ day}^{-1}$) from June to September. The BP/PP ratio is very low during the spring diatom bloom, while after the collapse of cyanobacteria in late summer to autumn, the BP/PP typically increases (Tammert and Kisand, 2004).

Genetic (PCR-DGGE of partial 16 S rDNA sequences) and functional fingerprints (CLPP by BIOLOG GN microplates) of the bacterioplankton enabled the identification of 36 different operational taxonomic units (OTUs) (Kisand and Nõges, 2004). The lowest numbers of OTUs (up to 10) occurred in July and the highest (up to 21) in November. Highly productive bacterial community preferentially utilized simple carbohydrates, whereas amino acids and organic acids involved in amino acid metabolism were preferably utilized during transition periods between winter and early spring, and late summer/early autumn when BP was relatively low but BB was high.

Zooplankton

A total of 307 zooplankton taxa have been identified in Võrtsjärv including 172 rotifers, (Rotifera), 47 cladocerans (Cladocera), 14 copepods (Copepoda), 73 ciliates (Ciliata), and 1 mollusc – *Dreissena polymorpha* juv.

Ciliates are studied in Võrtsjärv since 1995. There are 73 ciliate taxa found in Võrtsjärv with the greatest species

diversity occurring in June (Zingel and Nõges, 2010). Oligotrichs (the most common genera *Rimostrombidium*, *Limnostrombidium*, *Pelagostrombidium*, and *Halteria* and species *Codonella cratera* and *Tintinnidium fluviatile*) are the most numerous group (27–78%), being followed by prostomatids (11–25%), haptorids (4–34%), scuticociliates (0.3–22%), and peritrichs, the latter present only during warm seasons and never found in winter. The other ciliate orders found are Colpodida, Nassulida, Heterotrichida, Hymenostomatida, Hypotrichida, Pleutostomatida, and Suctorida. The biomass of ciliates is accounting for more than 60% of the total zooplankton (meta- and protozooplankton) biomass. Seasonally, the abundance of ciliates is highly variable (Table 3). Maximum ciliate abundance (285 cells ml^{-1}) and biomass ($15.4 \mu\text{g ml}^{-1}$) were found in August 2006 and the respective minimum values in February 1995 (0.8 cells ml^{-1} and $0.02 \mu\text{g ml}^{-1}$). Ciliate abundance peaks in spring (May) and reaches its maximum in late summer (July, August). Large-sized nanovorous oligotrichs dominate in spring. The summer peak is made up of small scuticociliates and oligotrichs, feeding mainly on picoplankton. The highest biomass values are not always coupled with the peak abundances, but with the occurrence of large ($>300 \mu\text{m}$) gymnostomes. A positive correlation between ciliates and phyto- and bacterioplankton shows that ciliate community is food-controlled. As both bacteria and phytoplankton are coupled with resuspension of lake sediments, the largely fluctuating water level influences the annual abundance of the ciliate community.

A total of 234 metazooplankton taxa belonging to planktonic and planktobenthic forms have been found in Võrtsjärv. The dominating species by number ($>20\%$ of total number) are the rotifers *Anuraeopsis fissa* (Gosse), *Keratella cochlearis* (Gosse), *Keratella quadrata frenzeli* (Eckst.), *Trichocerca rousseleti* (Voigt), *Polyarthra luminosa* Kut., *Polyarthra dolichoptera* Idels., and *Synchaeta verrucosa* Nipk., the latter two in winter. The biomass dominants ($>20\%$ of total biomass) are the cladocerans *Bosmina c. coregoni* Baird, *Bosmina longirostris* (Müller), *Chydorus sphaericus* (Müller), and *Daphnia cucullata* Sars, and the copepod species of genus *Mesocyclops*. All dominants are characteristic of eutrophic lakes. The number of simultaneously dominating species is small, and the functioning load is divided unevenly between species.

During 1994–2009, the mean metazooplankton biomass varied by season from 0.1 in winter to 1.7 g m^{-3} in summer, being on average 0.8 g m^{-3} (Table 3). The biomass of predatory zooplankton formed on average 18% of the total zooplankton biomass. The abundance is rather high while the biomass is low because of the large share of small-bodied rotifers to the whole zooplankton community. The mean individual weight is very small in Võrtsjärv, fluctuating between 0.7 and $3.2 \mu\text{g}$ with a mean value of $2.5 \mu\text{g}$ for the vegetation period (Haberman and Virro, 2004). According to the same authors, zooplankton production is low due to poor food conditions, with mean values

Võrtsjärv Lake in Estonia, Table 3 Seasonal statistics of main plankton variables in Võrtsjärv based on monthly monitoring data from 1994 to 2009. The year was split into 3-month seasons starting winter from December

Võrtsjärv Lake in Estonia, Table 4 Colonization of Võrtsjärv by aquatic macrophytes in 2006–2009 (T. Feldmann, unpublished)

Life form	Colonized area, km ²	Percentage of lake area
Emergent plants	11.26	4.17
Floating-leaved plants	3.49	1.29
Submerged plants	47.83	17.72
Total	62.6	23.2

ranging for herbivorous zooplankton from 0.03 to 1.6 g C m⁻² month⁻¹ and for predatory zooplankton from 0 to 0.2 g C m⁻² month⁻¹.

During the last 40 years, the zooplankton biomass has not undergone great changes, but the species composition has been reflecting the changes in the lake's trophic state. The species characteristic of oligo-mesotrophic waters have totally disappeared or their abundance is declining (Haberman and Virro, 2004). Among zooplankton groups, the share of copepods in zooplankton biomass has significantly increased in summer, autumn, and winter for the period 1995–2009, while the share of rotifers has decreased in winter. By numbers, the share of rotifers has increased in summer on the account of decreasing share of cladocerans.

Zoobenthos

The weighted average abundance ($\pm$ standard error) of the zoobenthos without large molluscs over all habitat zones was 804 ± 56 ind m⁻² and the wet biomass 6.48 ± 0.88 g m⁻² in 1973–2003 (Kangur et al., 2004). The weighting factors were based on the areal proportions of the main types of benthic habitats, considering that 15%

of the lake bottom area is accounted for by the shallow vegetated littoral, 22% by the vegetation-free hard bottom sublittoral deeper than 1 m, and the remaining 63% is the profundal with a bare mud bottom at depths larger than 1 m. Chironomidae and Oligochaeta with a few dominating species make up the bulk of zoobenthos in the lake. Larvae of Chironomidae, with about 150 larval forms identified in the lake, represent the most diverse, widely distributed, and abundant group, accounting for more than 60% of the total zoobenthos abundance and more than 80% of the biomass (Figure 6). The most important species, *Chironomus plumosus* L. constitutes 73% of the average zoobenthos biomass (up to 90% in some years), and its relative importance has been increasing in the course of eutrophication. This species has either one or two generations in Võrtsjärv. The sublittoral chironomid fauna is somewhat richer, but most chironomid taxa in Võrtsjärv are limited to different littoral habitats with specific communities found on sand, stones, and muddy sand or mud among the macrovegetation. The distribution of chironomid assemblages in Võrtsjärv has not changed much during recent decades. The Oligochaeta are notably surpassed by the Chironomidae in abundance. A total of 54 species of Oligochaeta have been recorded from the lake, most of them from the littoral. *Potamothenix hammoniensis* (Michaelsen) is almost the single oligochaete species in the profundal, forming about half of their individuals in the open region. On muddy sand bottom, *Psammoryctides barbatus* (Grube) and *Limnodrilus hoffmeisteri* Claparède are common, often accompanied by *Potamothenix hammoniensis*. The two former species prevail also in the littoral. Seventy species of the Mollusca have been recorded from Võrtsjärv including 34 species of Gastropoda and 36 of Bivalvia. Among gastropods, *Valvata piscinalis* (Müller)

Võrtsjärv Lake in Estonia, Figure 6 Percentages of main groups of bottom animals (without large Mollusca) by abundance (a) and biomass (b) in Võrtsjärv in 1973–2003. (Based on data from Kangur et al., 2004.)

is the most common. The large unionid clams *Unio tumidus* Philipsson and *Anodonta anatina* (L.) are common everywhere in the sublittoral and the littoral. The abundance of *Dreissena polymorpha* Pallas an invader first found in Võrtsjärv in the 1950s, gradually declined to a few single individuals found by the turn of the century. The average biomass of the large molluscs, 1.6 g m^{-2} in the whole lake, is four times less than the total biomass of all “small” benthic animals but four times more than that of the small molluscs.

The main reasons for seasonal fluctuations in the amount of Võrtsjärv zoobenthos are the emergence of chironomids and other aquatic insects in summer, and fish predation. Large annual fluctuations with average abundance ranging from 401 to $1,601 \text{ ind. m}^{-2}$ and biomass from 1.6 to 26.4 g m^{-2} in different years are determined mostly by the variability of *Chironomus plumosus* in the profundal, which revealed a clear 3–4-year periodicity. A general increasing trend in the biomass of Chironomidae and Oligochaeta and decreasing trend in Mollusca and other groups were noticeable until 1996 (Kangur et al., 1998); however, the amount of zoobenthos decreased again in Võrtsjärv during the late 1990s.

Fishes and fisheries

Currently, 31 fish species and one lamprey species inhabit Võrtsjärv and its tributaries permanently. Rainbow trout and carp, escaped from fish ponds, have been caught occasionally but do not spawn in the lake. Four species, pike (*Esox lucius* L.), eel (*Anguilla anguilla* (L.)), bream

(*Abramis brama* (L.)), and pikeperch (*Sander lucioperca* (L.)), are presently the main very abundant commercial fishes. Also, the second-rate commercial fishes, such as roach (*Rutilus rutilus* (L.)), burbot (*Lota lota* (L.)), and perch (*Perca fluviatilis* L.), with annual catches ranging between 2 and 20 tons, are abundant or very abundant. During the last 2–3 decades, ruffe (*Gymnocephalus cernuus* (L.)), bleak (*Alburnus alburnus* (L.)), and lake smelt (*Osmerus eperlanus* m. *spirinchus* Pallas) have become abundant or very abundant as well, but they have lost their commercial importance as the use of fine-meshed trawls is prohibited in the lake since the 1970s. The remaining 24 species are non-abundant or rare with no or very limited commercial importance. Asp (*Aspius aspius* (L.)) and wels (*Silurus glanis* L.) are fully protected all the year round (Järvalt et al., 2004).

The abundance of pike in Võrtsjärv depends mostly on water level in spring. At high water levels, the floodplains, which are the favorite spawning areas for pike, are extensively flooded. Large pike catches in Võrtsjärv follow periods of high water level, as a rule, with a 4–5-year lag, whereas a similar lag separates small catches from periods of low water level.

The construction of the Narva hydropower station in the early 1950s blocked the natural route of eel from the Baltic Sea to the lake. As a result, eel almost disappeared from the lake's fish fauna. At present, owing to the 43 million elvers and 2 million young eels introduced since 1956, eel has become the most important commercial fish in the lake, turning Võrtsjärv the main site of eel production in Estonia. The biggest annual catches of eel in Võrtsjärv have exceeded 100 t.

Bream is the most productive commercial fish in Võrtsjärv. Since 1974, all catch limitation on bream was lifted because it began competing seriously for food (first of all, *Chironomus plumosus* larvae) with the far more valuable eel. The unlimited catch had even a positive effect on bream through improved feeding conditions: its growth rate accelerated, and it became fleshier and tastier. Unlike pike, bream can successfully spawn also during low-water periods in the lake (Järvalt and Pihu, 2002). Võrtsjärv has now acquired several characteristics of a bream lake. It is not impossible that it will become a pikeperch–bream lake in the future.

Spawning of pikeperch in Võrtsjärv is favored by low water, which warms up sooner, enabling earlier spawning and extends the growing period of the fry (Järvalt and Pihu, 2002).

Ruffe as the most important consumer of zoobenthos in Võrtsjärv and the main food competitor for eel and bream is regarded as the most unwanted fish species in the lake.

In case low water level and a severe winter coincide, serious fish kills may occur in the lake. Fishery has reached an optimum level in Võrtsjärv. The profitability of fishery in Võrtsjärv depends mainly on the condition of the stocks of pikeperch, pike, and eel. Large predators control the number of rough small fish, while eel accounts for the bulk of the income from fishery.

Food web functioning

The transformation of energy fixed by primary producers within the food web of Võrtsjärv is ineffective (Figure 7). The production of herbivorous zooplankton and benthic macroinvertebrates is 40 times lower than the PP of phytoplankton. The efficiency of the predatory links is much higher. The production of predatory zooplankton constitutes more than 10% of the production of herbivorous zooplankton, while the production of non-piscivorous fish makes up 12% of the production of its food objects (zooplankton, benthic invertebrates), and the production of piscivorous fish forms 13% of the production of non-piscivorous fish. It is evident that the low efficiency of the food chains in Võrtsjärv is the result of the large number of links at the beginning of the chain. Most of the organic matter produced by phytoplankton is not consumed by herbivores but enters the pool of detritus and is consumed in detrital food chains represented by the microbial loop and benthic animals. This is reflected by the high production of bacteria (70% of primary production) and the extremely abundant ciliate community. In Võrtsjärv, microbial loop prevails in the food web, and ciliates have a major role in it (Kisand and Zingel, 2000). The most abundant ciliate species in Võrtsjärv are euplanktonic pico- and nanovores, which are well adapted to the shallow and highly turbid ecosystem. Grazing studies (Zingel et al., 2007) showed that

ciliates are able to graze daily more than 100% of the bacterial biomass production, and 9.3% of the bacterial and 20.7% of the nanophytoplankton standing stock, whereas metazooplankton grazes only a minor part of the standing stocks of bacterioplankton and nanoalgae (0.1% and 1%, respectively).

Research

The first data on Võrtsjärv fisheries, hydrology, and aquatic vegetation were published by Baltic German naturalists in the eighteenth and nineteenth centuries. The first monograph by Mühlen and Schneider (1920) was based on the complex expedition organized by the Lake Commission of the Estonian Naturalists' Society in 1911–1913. From the 1920s to 1950s, only a few investigations were carried out on Võrtsjärv. The bulk of the present long-term data on the lake has been collected during the existence of the Centre for Limnology (previously Võrtsjärv Limnological Station) since the 1960s. The results have been published in two monographs (Timm, 1973; Haberman et al., 2004) and numerous scientific papers. Võrtsjärv has been a case study lake in EU-scale research projects ECORAME, CLIME, and REFRESH. Võrtsjärv has been included in the World Lakes Database of the International Lake Environment Committee (ILEC) <http://www.ilec.or.jp/database/eur/eur-47.html>.

WATER BALANCE OF LAKES

Lars Bengtsson
Department of Water Resources Engineering, Lund
University, Lund, Sweden

Description

The most basic in river basin hydrology is the water balance – and so it is for lakes. Most lakes have outflows, but some of the most famous lakes of the world are terminal lakes with no outflow, for example, the Caspian Sea, Lake Chad, and the Dead Sea. The water level in the overflowing lakes is rather stable, while the water level in the terminal lakes varies with the climate. In some lakes with small upstream catchment, the inflow to the lake is dominated by the precipitation on the lake, but usually inflow rivers are the dominating source of inflow to a lake. Some lakes only have subsurface inflow, but in most lakes, the most important inflow is from rivers. There also exist kettle lakes, which are part of the groundwater system with only subsurface inflow and outflow.

The water balance of a lake is

$$\begin{aligned}\frac{dVOL}{dt} &= A(h) \frac{dh}{dt} \\ &= Q_{in} - Q_{out}(h) + Q_{gwin} - Q_{gwout} + (P - E)A(h)\end{aligned}$$

VOL is the lake volume, A is the surface area which varies with the lake level, Q is surface flow, Q_{gw} is subsurface flow with different index for inflows and outflows, P is precipitation on the lake surface, and E is evaporation from the lake. There is seldom any groundwater seepage out of a lake. Groundwater inflow is significant when

there are springs or when the lake is situated on the border of an esker.

The natural river outflow is a function of the lake level above the outlet sill. If there is subsurface outflow, this subsurface outflow only very minor depends on the lake level. When the surface area and the outflow are known functions of the lake level, the lake level variation can be determined from the water balance. Most often the precipitation on the lake and the evaporation are nonsignificant compared to the inflows and outflows, so the water balance is simply

$$A(h) \frac{dh}{dt} = Q_{in} - Q_{out}(h)$$

Solving this equation with a short time step is called lake routing. The lake level and, from that, the outflow are determined. In a lake with outflow, the lake level, h, is usually given as the level above the outlet sill.

A lake with no outflow is a terminal lake and situated downstream in a closed basin, endorheic basin. Such a lake is a sink to most pollutants. The water is usually salty. Water leaves the lake only by evaporation. The water balance is

$$A(h) \frac{dh}{dt} = Q_{in} + (P - E)A(h)$$

The steady-state lake level area is then

$$A_{lake} = \frac{Q_{in}}{E - P}$$

The inflow is the basin precipitation – the evapotranspiration losses over the upstream basin – eventual water withdrawals. The lake is the lower part of a basin. If this endorheic basin including the lake has the area A_{basin} ,

the specific basin runoff is q , and if the lake has the variable surface area A_{lake} , then the part of the basin which constitutes the terminal lakes can be given as

$$\frac{A_{\text{lake}}}{A_{\text{basin}}} = \frac{q}{q + E - P}$$

Terminal lakes are found in dry climate. Often the lake area constitutes a not very small part of the river basin. Say the specific runoff is 100 mm/year, the lake evaporation 1,000 mm and the precipitation on the lake 500 mm. The lake area is then 20% of the river basin. In a warmer and drier period, the specific runoff may reduce to 70 mm, the evaporation may increase to 1,100 mm, and the precipitation may reduce to 400 mm. The lake area relative to the basin area then decreases to less than 10%, which means that the lake area is reduced 50%.

WATER BALANCE OF THE LAURENTIAN GREAT LAKES

Vincent Fortin¹, Andrew D. Gronewold²

¹Meteorological Research Division, Environment Canada, Dorval (Québec), Canada

²Great Lakes Environmental Research Laboratory, NOAA, Ann Arbor, MI, USA

Introduction

Surface water elevation dynamics of the Laurentian Great Lakes exhibit long-term persistence on decadal time scales, and the changes in surface water elevation over these time scales are driven mainly by climate dynamics.

Understanding Great Lakes water elevation dynamics on shorter time scales (such as monthly and annual scales) is commonly based on a cumulative assessment of the individual components of the net supply of water (i.e., precipitation, evaporation, and runoff) within the Great Lakes basin.

Great lakes water levels

The surface water elevations (hereafter referred to as “water levels”) of the Great Lakes are closely monitored by both the United States (through NOAA’s National Ocean Service) and Canada (through the Canadian Hydrographic Service). Monthly mean lake-wide levels, obtained by averaging a subset of US and Canadian gauges from around the lakes, can be obtained from the US Army Corps of Engineers:

<http://www.lre.usace.army.mil/greatlakes/hh/greatlakes/waterlevels/>

Figure 1 illustrates how lake levels have changed over time from 1948 to 2008. Water level data is available prior to 1948; however, we focus here on the 1948–2008 time period because it is the only period for which water levels and estimates for all components of net basin supply are readily available. Lake Michigan and Lake Huron have the same mean water level, as the lakes are connected at the Straits of Mackinac. Note that in Figure 1, we use a separate vertical axis for Lake Ontario, which is on average approximately 100 m lower than Lake Erie (due primarily to the drop in elevation over Niagara Falls). The thin, gray horizontal lines in Figure 1 indicate the long-term average water level for each lake from 1948 to 2008.

In general, water levels over the past decade were lower than the 1948–2008 average for all lakes but Lake Ontario. Long-term persistence on decadal time scales is also seen for all lakes, although more pronounced cycles are apparent for Lake Michigan-Huron. Lag-1 autocorrelation of mean annual levels ranges from 0.5 for Lake Ontario to 0.8 for Lake Michigan-Huron. Autocorrelation is in fact significantly larger than zero at the 95% level from lag-1 to lag-5 for Lake Michigan-Huron over this time period. These results collectively suggest a persistent, non-random pattern of annual water level on the Great Lakes.

Net basin supply

As with most lakes, the lake-wide average water level (H) of each of the Laurentian Great Lakes increases if the net total supply (NTS) of water to the entire basin (including the lake itself) is larger than the flow at the outlet of the lake (O). However, water level also varies with the temperature of the lake, which affects its density and, therefore, its volume. The change in water levels can therefore be expressed as follows (note that each term in the following expression, is in units of millimeter):

$$\Delta H = NTS - O + \Delta H_T$$

where ΔH_T reflects the impact of thermal expansion.

Water Balance of the Laurentian Great Lakes, Figure 1 Time series of Great Lakes monthly average lake-wide water levels, 1948–2008.

NTS can be decomposed into an overlake precipitation component (P), an overlake evaporation component (E), and a runoff component (R_{total}). The runoff component includes contributions from tributaries upstream of, and discharging directly into, each lake. This decomposition leads to the following expression:

$$\Delta H = P - E + R_{total} - O + \Delta H_T$$

Other terms of the water balance, such as consumptive use and net groundwater flux into the lakes, are relatively small compared to the components identified above, and are therefore generally ignored (IUGLS, 2009).

NTS can be further decomposed into runoff from the lake's own watershed (R), inflow coming from the upstream lake (I), and any nonnatural diversion of water into or out of adjacent watersheds (D). Hence:

$$\Delta H = P - E + R - O + I + D + \Delta H_T$$

The first three terms in the equation above correspond to the water cycle within a lake's individual basin, including the lake itself but not including the watershed of any upstream lake or diversion, and are collectively referred to as the net basin supply (NBS):

$$NBS = P - E + R$$

NBS is the primary driver of lake levels on monthly and longer time scales, as inflows and outflows are essentially

controlled by lake levels. Indeed, while Lake Superior and Lake Ontario outflows are regulated, which tends to reduce natural variability of lake levels, regulation has little impact on long-term trends: The climate, hence, essentially dictates what happens to lake levels, although other factors such as conveyance changes in the channels connecting the lakes and glacial isostatic adjustment do play a role (IUGLS, 2009). This relationship suggests that lake levels can be simulated and forecasted (Gronewold et al., 2011) on monthly time scales using monthly NBS sequences as input to a lake routing model in which regulation effects are predicted from lake levels, and diversions are prescribed.

The component and the residual methods

NBS can be computed by either estimating each of the three components P , E , and R (the component method), or as a residual of the water balance equation (the residual method), indicated in the following expression:

$$NBS = \Delta H + O - I - D - \Delta H_T$$

The thermal expansion term ΔH_T is generally ignored because it is close to zero on an annual time scale, but it can be significant on monthly time scales, given the strong annual cycle in water temperature. For example, according to Bruxer (2010), Lake Erie water levels increase on average by about 40 mm from May to July due to thermal expansion, and lose as much volume due

to thermal contraction between September and November, which corresponds to approximately 15% of the May-to-July *NBS*, but close to 40% of the September-to-November *NBS*.

Note that the residual method cannot be used to estimate separately *NBS* for Lake Michigan and Lake Huron, which are connected at the Straits of Mackinac. Hence, when it comes to assessing the water balance of the Great Lakes, Lake Michigan-Huron is generally considered to be a single body of water, although the component method can be used to obtain separate estimates of *NBS* for both lakes. A separate water balance is, however, commonly estimated for Lake St. Clair, so that *NBS* is generally computed for five lake systems: Lake Superior, Lake Michigan-Huron, Lake St. Clair, Lake Erie, and Lake Ontario. However, because Lake St. Clair and its watershed are significantly smaller than the other Great Lakes, it is often incorporated into the Lake Erie system, particularly in time series plots and other graphical representations of *NBS* and water levels.

Components of net basin supply

Residual *NBS* can be computed from hydrological information alone (levels and flows); however, residual *NBS* estimates on time scales shorter than a month are often

highly uncertain and variable. The component *NBS* method requires a mix of meteorological and hydrological observations, integrated in a hydrometeorological model (Hunter and Croley, 1993; Pietroniro et al., 2007), in order to accurately estimate each component, but provides an additional level of understanding as to why lake levels change over time, and makes it possible to forecast *NBS* and lake levels on monthly to seasonal time scales (Gronewold et al., 2011). Long-term estimates of each *NBS* component, computed using techniques described by Hunter and Croley (1993), can be obtained from NOAA's Great Lakes Environmental Research Laboratory (GLERL):

<http://www.glerl.noaa.gov/data/arc/hydro/mnth-hydro.html>

Figure 2 includes GLERL's long-term (i.e., 1948–2008) average monthly *NBS* estimates and each of its components, and provides an indication of their seasonal dynamics. Results are shown for (a) Lake Superior, (b) Lake Michigan-Huron, (c) Lake Erie and St. Clair, and (d) Lake Ontario. It can be seen that the annual peak in *NBS* coincides with the annual peak in runoff for all lakes. For the Upper Great Lakes (all lakes but Lake Ontario), the annual minimum in *NBS* coincides with the annual peak in overlake evaporation.

Water Balance of the Laurentian Great Lakes, Figure 2 Average monthly net basin supply (NBS) and NBS components for the North American Laurentian Great Lakes, averaged over the period 1948–2008.

For all lakes, mean annual overlake precipitation is larger than mean annual overlake evaporation but, more importantly, mean annual runoff is larger than the mean annual net overlake precipitation ($P - E$). On an annual basis, the ratio of net overlake precipitation to NBS is, on average, roughly 20% for Lake Superior and Michigan-Huron, roughly 1% for Lake Erie and St. Clair, and roughly 10% for Lake Ontario. In all cases, the contribution of net overlake precipitation is much smaller than the ratio of the lake area to the watershed area. Hence, for the purpose of understanding and predicting the water balance of the Great Lakes on an annual scale, it is critical to accurately assess the runoff component. However, all three components can have a significant influence on NBS for individual months. In fact, NBS is often negative in fall and winter months, with overlake evaporation being larger than $P + R$.

Natural variability, uncertainty, and climate change

Figure 3 includes annual mean net overlake precipitation ($P - E$), runoff, and NBS for each lake from 1948 to 2008, and indicates a general decrease in annual net overlake precipitation ($P - E$) for Lakes Michigan-Huron

and Superior over the last several decades, with a noticeable increase in the frequency of negative net overlake precipitation for these two systems from roughly 2000 to 2008. On Lake Ontario, 2007 was the first year, for the period 1948–2008, with negative net overlake precipitation.

Important differences are in fact seen in NBS from one decade to the next for all lakes, and reflecting these dynamics in simulation and forecasting models is an important aspect of Great Lakes water resources management and planning. Shifting-level models, for example, have been used to describe, simulate, and predict NBS for water management purposes (Sveinsson et al., 2005; Fagherazzi et al., 2005), and represent a family of stochastic models that allows the mean of key process variables to change abruptly over time. Other modeling applications, including a time series segmentation algorithm based on the shifting-level model (Kehagias and Fortin, 2006), reveal that all lakes but the smaller Lake St. Clair have seen an upward shift in evaporation. This increase in evaporation is consistent with observed decreases in seasonal ice cover on all lakes (IUGLS, 2009), a phenomenon which can lead to increased heat input into the lake (Desai et al., 2009).

Water Balance of the Laurentian Great Lakes, Figure 3 Total annual net basin supply (NBS) and NBS components for the North American Laurentian Great Lakes for the period 1948–2008.

Figures 2 and 3 underscore the strong link between runoff and *NBS* for all lakes. Less obvious is the fact that net overlake precipitation adds variability to the signal. Indeed, the coefficient of variation of *NBS* (i.e., the standard deviation of *NBS* divided by its mean), is higher than the coefficient of variation of runoff for all lakes. Autocorrelation is therefore also lower for *NBS* than for runoff. The autocorrelation of annual runoff is in fact significantly different from zero at the 95% level for all lakes, but not the autocorrelation of annual *NBS*, suggesting that some of the persistence at the annual scale can be explained by the filtering effect of the watershed, although this signal could also be related to persistence in overland precipitation or evapotranspiration. This is consistent with the findings of Vogel et al. (1998), who found that annual streamflow records in the Great Lakes region showed higher persistence than in any other region of the conterminous United States.

All diagnostics based on the component *NBS* method are, however, limited by the accuracy with which each component is estimated. Indeed, the estimates we present here are simply one set of estimates, based on one set of model assumptions and one set of input data. Other model alternatives and data sources could be (and, increasingly, are being) used. Overlake precipitation, for example, can be estimated from near-shore precipitation gauges, radar and satellite imagery, and other sources, while runoff can be estimated from streamflow observations or conceptual rainfall-runoff models, although each method has unique intrinsic sources of uncertainty and variability (Neff and Nicholas, 2005). There is however no operational observational network on which to base estimates of overlake evaporation, and therefore, these estimates are based on hydrometeorological models calibrated to other observed variables, such as water surface temperature. Recent observations using an eddy-correlation system installed on a light house on Lake Superior (Blanken et al., 2011; Spence et al., 2011) suggest, however, that current operational models being used to assess overlake evaporation tend to overestimate evaporation in winter, and in particular when the latent heat flux is strongest, but do capture the synoptic-scale fluctuations in overlake evaporation. Even after accounting for this potential bias, however, there is a strong evidence of a recent increase in annual overlake evaporation within the Great Lakes basin.

As indicated previously, relatively recent increases in overlake evaporation and other *NBS* component dynamics are likely related more to shifting climate dynamics over decadal time scales than to seasonal or annual variability. Recent efforts to predict future *NBS* dynamics under alternative climate scenarios, including the use of hydrometeorological models forced by general circulation models, suggest a broad range of potential future *NBS* sequences and water levels (Angel and Kunkel, 2010). These models, however, may not appropriately represent basin evapotranspiration over decadal time scales (Lofgren et al.,

2011) and more precise climate-related *NBS* and Great Lakes water level projections might be expected from regional climate model simulations, many of which were recently conducted by both the United States and Canada as part of the International Upper Great Lakes Study (IUGLS, 2009).

WATER EXCHANGE BETWEEN LITTORAL ZONE AND OPEN LAKE WATER

Yukie Tanino

Department of Earth Science and Engineering, Imperial College London, London, UK

Definition

Exchange flow – Predominantly horizontal countercurrent flows.

Density-driven flow – A flow driven by predominantly horizontal density gradients. Synonyms include gravity current and buoyancy-driven flow.

Thermally driven current – A gravity current in which the density gradient is the direct result of a spatial gradient in temperature.

Introduction

Adjacent littoral and pelagic (open) waters may have very different physical and chemical properties because of differences in proximity to land, depth, and vegetation density. For example, dissolved oxygen and pH were distinctly lower within a *Glyceria aquatica* stand in a pond than in the adjacent open water (Dvorák, 1970). Gradients have also been reported in turbidity, conductivity, alkalinity, and concentrations of various chemical constituents, such as Cl, K, Na, NO₃-N, total phosphorus, PO₄-P, and dissolved organic carbon across the littoral zone (Cardinale et al., 1997; James and Barko, 1991; Ng et al., 2010; Klosowski, 1992). In the presence of such long-range spatial gradients, advection between littoral and pelagic regions results in the net flux of constituents and physical properties over large distances.

Two types of exchange flows

The two main types of littoral–pelagic exchange flow in a lake are flows driven by stress imposed on the water surface by the wind and flows driven by a horizontal gradient in water temperature (Figure 1). The latter are commonly referred to as thermally-driven flows or gravity currents. In a closed system, these flows are accompanied by flow in the opposite direction so that mass is conserved.

Water Exchange Between Littoral Zone and Open Lake Water, Figure 1 An exchange flow between the pelagic zone and the littoral zone may be driven by wind-induced stress at the water surface or a littoral–pelagic temperature gradient. In this illustration, the wind and the density gradient due to the temperature difference drive flow in opposite directions.

Wind-driven surface currents

Wind blowing over the surface of a lake induces stress, driving water below it in the same direction. The speed of the wind-driven flow decays with increasing depth, then reverses direction, as illustrated in Figure 1.

The speed of a wind-driven surface current is expected to increase with increasing wind speed, with 2% often cited as a typical ratio. Indeed, wind factors in the range 1.0–2.0% have been reported in selected field sites in the presence of winds at 1–6 m/s (Haines and Bryson, 1961; George, 2000, 1981). Further, several studies have reported the existence of a critical wind speed at which the surface current speed becomes constant (George, 2000) or begins to decrease sharply (Haines and Bryson, 1961). In Lake Mendota, Wisconsin, the critical wind speed was 5.7 m/s, with a corresponding surface current speed of 16.0 cm/s (Haines and Bryson, 1961). In Esthwaite Water in Cumbria, the critical wind speed was 3 m/s (George, 2000). In a more extreme case, surface current speeds in Eglwys Nynydd reservoir in Port Talbot were constant above a wind speed as low as 2 m/s (George and Edwards, 1976).

Thermally-driven flows

In inland aquatic systems, gradients in temperature, hence density, commonly arise from spatial variability in water depth (e.g., Monismith et al., 1990; Roget and Colomer, 1996), groundwater discharge (Roget et al., 1993), light compensation depth (e.g., MacIntyre et al., 2002; Nepf and Oldham, 1997), shading by floating macrophytes (Coates and Ferris, 1994; Dale and Gillespie,

Water Exchange Between Littoral Zone and Open Lake Water, Table 1 Selected field studies reporting thermally driven currents

Site	Conditions	Current speeds	Attributed origin of current	Reference
Eau Galle Reservoir, WI	Nighttime, calm conditions	0.1 cm/s intrusion current; 0.03, 0.05 cm/s surface return flow	Differential nighttime cooling	James and Barko, 1991
Lake Krankesjön, Sweden	Clear, summer, daytime, 0.5–2.2 m/s winds	0.1–2.3 cm/s surface flow toward littoral region	Temperature difference of 0.5–1.2°C across the littoral–pelagic interface. Open water is warmer	Lovstedt and Bengtsson, 2008
Clear Lake, CA	Summer, daily wind speed variations between 0 and 10 m/s	Thermally-driven flows of up to 10–15 cm/s	Diel oscillation between thermally-driven (night to early morning) and wind-driven circulation (daytime)	Rueda et al., 2003
Lake Banyoles, Catalonia	Overturn	1–10 cm/s bottom currents	Differential cooling. Variations in bottom current speed controlled by wind direction and speed	Roget et al., 1993

**Water Exchange Between Littoral Zone and Open Lake Water, Figure 2** Vertical profiles of flow velocity, as described by a mathematical solution for laminar flow conditions in an idealized, sparsely vegetated littoral region with a horizontal temperature gradient of 25°C/km (Tanino, 2004). The ordinate is distance from the bed normalized by the total water depth. The density gradient is negative, i.e., denser (cooler) water is to the left. Wind velocity is positive, with speeds as indicated above each profile.

1976) and dense canopy of reeds (Lovstedt and Bengtsson, 2008), or sheltering from the wind (MacIntyre et al., 2002). In the example illustrated in Figure 1, the temperature of the water in the shallower littoral zone increases more rapidly during daytime from solar radiation than that of the open water, and a horizontal temperature gradient develops between the littoral zone and the pelagic zone. As the littoral water warms, it becomes less dense and propagates toward the open water along the surface. The adjacent cooler water flows in below it in the opposite direction to conserve mass, thus establishing a circulation cell. At nighttime, the littoral water, which cools faster, flows toward the pelagic region as a bottom current.

Thermally-driven motion is generally regarded to be small compared to wind-induced currents. However, the

former may be significant when wind-induced flows are small. For example, in Esthwaite Water, surface currents at a given wind speed were 0.2–2 cm/s greater when a near-surface thermocline was established in the littoral region (George, 2000). These periods coincided with calm, warm conditions – when the open water was several degrees cooler than the littoral water – which are conditions favorable to thermally-driven flows. If the increase in current speed is interpreted to be due to thermally driven motion, then George (2000)’s observations indicate that thermally driven flows can exceed wind-induced flows. Also, conditions to induce thermally-driven flow may occur frequently during favorable seasons (e.g., James et al., 1994). For these reasons, thermally-driven flows may constitute an important pathway in lake-scale

chemical cycles despite their low velocities. For example, the net flux of total phosphorus attributed to nighttime convective circulation in July was estimated to correspond to 22% of the mean summertime lake-wide internal loading in Eau Galle Reservoir (James and Barko, 1991).

Selected field studies are listed in Table 1.

Direct interference of wind on thermally-driven flows

The interaction of wind and thermally-driven flows is inherently complex. The simplest arises from the requirement that the stress at the air/water interface must equal the wind stress. In the absence of wind, the density gradient creates a two-layered system with an undercurrent and surface current propagating in the positive and negative direction, respectively (e.g., Figure 2a). When wind stress acts in the same direction as the thermally-driven surface current, it merely increases the flow speed. When the wind stress acts against the surface current, the possible outcomes are more varied. Sufficiently low wind stress simply reduces the water speed at the surface. Sufficiently high wind stress will override the underlying thermally-driven circulation and induce a surface current in the downwind direction (Figure 2c). The behavior of the flow at intermediate wind stress is not obvious. For example, a mathematical solution of an idealized system, under laminar flow conditions within a region of homogeneous sparse vegetation, predicts a three-layered flow structure (Figure 2b).

Such interactions between wind stress and underlying thermally-driven motion were proposed to explain the diel variation in a density-driven bottom current from the shallow, persistently cooler northern lobe to the deeper southern lobe in Lake Banyoles, Catalonia (Roget et al., 1993). When the wind blows in the opposite direction as the bottom current, a single circulation cell is expected to develop across the two lobes, with wind stress enhancing the preexisting northward surface return current. When the wind blows southward, Roget et al. (1993) proposed a lake-scale circulation comprised of two cells. The first comprises the thermally-driven bottom current and a return current that flows immediately above it. This return current flows parallel to the sloping bed, emerging at the surface within the northern lobe. The second cell comprises a wind-driven surface current southward and a return flow above the return flow of the first circulation cell.

Summary

Exchange of water between the littoral and pelagic zones of a lake is predominantly driven by wind stress and horizontal gradients in temperature that may arise from differential heating and cooling. The contribution from the wind typically dominates, but significant thermally-driven flows have been observed in selected sites under calm conditions. The interaction of wind and thermally driven motion can give rise to complex circulation patterns.

Lancaster, UK

Definition

European-wide legislative framework seeking more integrated, rationalized, and sustainable management of water in the twenty-first century

Context and background

Water management is one of the oldest and most established areas of environmental policy in the European Union (EU). Starting in the 1970s, EU water policy evolved from an initial concern for the protection of human health via common drinking water standards. In the late 1980s, the focus moved toward the aquatic environment itself and the use of emission limit values (ELVs). Finally, from the mid-1990s onward, policy was reoriented toward the development of a more holistic and strategic approach that recognizes the interconnections between surface and ground water, water quantity and quality, and the impacts of land-based activities on the water environment (McCormick, 2001).

The Water Framework Directive (WFD) is the centerpiece of the EU's integrated approach to water protection and management. It is expected to provide the basic policy framework for most of the twenty-first century, albeit with modifications as experience is gained and new requirements emerge in response to climate change and human uses of water. Formally adopted as EU policy in 2000, the WFD aims to protect all inland and coastal surface waters and groundwater; to achieve good ecological, chemical, and quantitative status for waters by 2015; to establish a system of water management based on river basin units; to combine ELVs with environmental quality standards; to ensure water prices provide adequate incentives to secure efficient uses of water; to involve

citizens more closely in decision making; and to streamline legislation (European Community (EC), 2007). Two additional areas needing new and more specific legislation were identified within the WFD: Priority Substances (Article 16) and Groundwater (Article 17). A new Groundwater Directive (2006/118/EC) was adopted in December 2006, and a Priority Substances Directive (2008/105/EC) was agreed in December 2008. The scope of the WFD has been further extended with the adoption of a Directive on the assessment and management of floods (2007/60/EC) and a Marine Strategy Framework Directive (2008/56/EC).

Implementation of the WFD

An implementation timetable was detailed within the text of the WFD, specifying deadlines by which key stages of the Directive should be achieved within Member States. Despite this Europe-wide plan for implementation, the success and technical content of the implementation process has differed substantially among individual Member States (EC, 2007). Implementation of the WFD requires that Member States:

Identify river basin districts and competent authorities

Management under the WFD is organized at the spatial scale of River Basin Districts (RBDs), perceived as a natural spatial unit for holistic and coordinated management of land and water. Member States were required to define RBDs on the basis of river catchments, using surface-water hydrological divides to identify the area of land from which water drains to a river. Across the EU, RBDs vary from single river catchments to combinations of multiple river catchments, and from less than 1,000 km² to over 800,000 km², with 40 RBDs crossing international borders and necessitating collaboration between Member States to deliver coordinated management at the RBD scale (EC, 2007). Competent authorities (CAs) responsible for administering the WFD have been identified for each RBD, with arrangements varying from one CA per RBD, through multiple CAs per RBD, to one CA for multiple RBDs (EC, 2007).

Identify water bodies, typologies, and reference conditions

Individual water bodies (WB) are defined within each RBD, and across the EU, 70,000 surface WBs have been identified of which approximately 15% are lakes (EC, 2007). Water bodies are categorized under the WFD as a lake, reservoir, stream, river or canal, part of a stream, river or canal, a transitional water, stretch of coastal water, or volume of groundwater (EC, 2000). Typology schemes are outlined for each WB category within the WFD, enabling Member States to group WBs with similar natural characteristics into a smaller number of water body types. For example, lake WB typologies are based largely on physical characteristics, including altitude, depth, and size

(EC, 2000). Separate WB categories exist for artificial and for heavily modified WBs. Heavily modified WBs are those where significant modification to the physical characteristics of the WB has occurred, and where the changes required to meet default objectives under the WFD would significantly adversely affect one or more human uses of that WB (UKTAG, 2008). Some Member States have designated over 50% of their WBs as heavily modified (EC, 2007), with implications for the objectives sought for these WBs (see below). Water body type-specific reference conditions must be defined under the WFD, against which the current status and future change in status of a WB are assessed. Reference conditions define biological, physicochemical, and hydromorphological conditions within a WB type in the absence of significant human pressure, and have been identified through analysis of existing non-impacted sites, through modeling, or through expert judgment.

Characterize pressures

Within each RBD, an assessment of the significant human-induced pressures acting on a WB, and the consequent risk that the WB will fail to meet the default objectives of the WFD, has been made. These risk assessments have demonstrated that approximately 40% of surface WBs across the EU are at risk of failing to achieve the default WFD objectives, but that this figure exceeds 70% in a number of Member States (EC, 2007). The pressures responsible for the risks of failure are diverse, including point and diffuse source pollution, morphological and hydrological modification, and the presence of alien species, and are derived from a range of activities spanning flood defense, mining, agriculture, urban development, and power generation. Limited data meant that the first risk assessment for 30% of the surface WBs across Europe was inconclusive (EC, 2007).

Monitor and classify the status of water bodies

The status of surface WBs under the WFD is defined by two components: ecological and chemical status. The ecological status classification is given by the lowest classed element from assessment of: biological quality elements (in lakes including fish, benthic macroinvertebrate, and phytoplankton communities); hydromorphological quality elements; and general chemical and physicochemical quality elements that support the biological quality elements, such as dissolved oxygen and total phosphorus concentrations in lakes (UKTAG, 2009). Chemical status is defined using a pass/fail system against environmental quality standards for priority substances and other EU-level dangerous substances, with the lowest classed substance determining chemical status. Overall surface water status under the WFD is given by the lower of either ecological or chemical status. This is a demanding classification scheme in which a failure to meet WFD objectives for one quality element results in an overall failure of the WB. Implementation of this classification scheme in the first planning cycle of the

WFD indicated that many WBs across Europe currently fail to meet the status required under the WFD. For example, within the Humber RBD in England, only 18% of surface WBs were classified as being at good status in 2009 (Environment Agency, 2009). Data for classification of WBs are provided by monitoring networks established within each Member State. *Surveillance monitoring* involves collection of data for all quality elements that contribute to status classification for a WB type, and builds on existing monitoring networks in Member States. *Operational monitoring* focuses on quality elements believed to be most sensitive to the pressures acting on a WB, and is designed to classify a WB at risk of failing to meet the objectives of the WFD. *Investigative monitoring* responds to unplanned events, such as pollutant spills, and is also used where the cause of a failure in a WB is not well understood (UKTAG, 2009).

Agree objectives and programmes of measures

The minimum requirement under the WFD is to prevent any further deterioration in the status of WBs. Beyond this, default objectives for each WB are defined. For surface WBs, this is to achieve good ecological and chemical status by 2015, and for groundwater bodies, good chemical and quantitative status by 2015. For artificial or heavily modified WBs, the default WFD objective is to achieve good ecological potential by 2015. Ecological potential is assessed using the mitigation measures that are in place to reduce the hydromorphological pressures on a WB. Where all applicable measures are in place, the WB is classified as being at good ecological potential or above; where one or more measure is not currently in place, the WB is classified as less than good ecological potential (UKTAG, 2008). If achieving default objectives under the WFD is deemed to be either technically infeasible or disproportionately costly (see below), alternative objectives can be defined. These include setting an objective that is lower than good status, or extending the timescale over which good status is achieved. For WBs that are already classified as being at good or better ecological status/potential, the WFD requirement of no deterioration in status applies. Protected area status under the WFD can be given to areas to safeguard their use (e.g., in the supply of drinking water), or because they contain important habitats or species. These areas are managed to deliver WFD objectives alongside existing objectives derived from previous EC legislation, such as the Habitats or Freshwater Fish Directives. Management actions to be undertaken as part of the WFD are defined as measures, and a programme of measures needs to be created for each RBD to ensure WB objectives are achieved. The WFD allows for economic and social appraisal of these measures (see below). It is on the basis of these appraisals that the measures needed to achieve good ecological status/potential can be classified as technically infeasible or disproportionately costly, offering the opportunity to set alternative objectives.

Conduct economic appraisals and apply economic instruments

Economic analysis is a significant feature of the implementation process, and references to economic principles (e.g., polluter pays), approaches (e.g., cost-effectiveness analysis), and tools (e.g., water pricing) appear throughout the text of the WFD. A detailed and robust economic analysis of water use and management is regarded as an essential aid to decision making (EC, 2003a), which not only will inform the preparation of the plans under the WFD but will also help to justify the basic and supplementary actions included in the programme of measures. Under Article 5, an analysis of water uses within each RBD was required (by 2004), with information required on the economic importance of water uses, projected trends and associated costs of water uses to 2015, and current levels of cost recovery for the range of water services. The results of the economic analysis are used within the river basin characterization process and are subsequently presented in the plans for each RBD. In cases where significant water management issues and/or risks of noncompliance with ecological, chemical, or quantitative objectives are identified from the characterization process, additional economic analysis is required as an integral part of the development of a programme of measures. Furthermore, the scope of the programme of measures is extended to include the recovery of the costs of water services, including environmental costs, under Article 9. Under this provision, water pricing arrangements must be put in place to provide incentives for efficient water use and different categories of water users (agriculture, domestic, industry) must contribute to the recovery of costs by 2010. The programme of measures includes two elements: (1) basic measures which comprise of existing EU Directives plus national standards, regulations, registers, and permitting arrangements, and (2) supplementary measures which include additional regulatory, economic, or voluntary measures which may be necessary to achieve the objectives specified for the WBs within a RBD. Each proposed measure, and the overall programme of combined measures, must be subjected to a cost-effectiveness analysis in order to demonstrate its viability. In cases where elements are shown not to be economically justified, the programme of measures must be adjusted accordingly. Under Article 4, the results of this analysis may also be used to seek derogations (time extensions and/or lower environmental objectives, see above) if it is shown that the implementation of the programme of measures would have serious economic or social impacts. Similarly, the economic analysis can be used to seek exemptions to avoid restoring heavily modified WBs where the costs could substantially outweigh the benefits.

Produce river basin management plans through an iterative planning process

The outcomes of the planning process described above need to be recorded for each RBD within a River Basin Management Plan (RBMP). The RBMP has no statutory

power in itself but should seek to set the framework within which existing powers are exercised to deliver the objectives of the WFD. A RBMP should: (1) provide an overview of the objectives for each WB and the programme of measures necessary to meet these objectives, (2) set the strategic policy framework for decisions affecting the water environment, and (3) report to the EC on implementation of the WFD (Defra, 2006). The river basin management planning process operates on an iterative 6-year cycle, involving assessment of WB status and pressures, drafting of RBMPs for consultation, implementation of measures, and review. The first RBMPs to emerge from this process were published in 2009, with subsequent plans due for publication in 2015, 2021, and 2027.

Provide information and enable public participation

The entire implementation process is to be conducted in an open and transparent manner, as this is believed to offer the strongest prospect of both commitment to action and environmental improvement. The 1998 Aarhus Convention on Access to Information, Public Participation in Decision-Making and Access to Justice in Environmental Matters led to the adoption of EU Directive 2003/4/EC on public access to environmental information and EU Directive 2003/35/EC on providing for public participation in environmental plans and programmes. The provisions of both of these Directives are reflected in Article 14 of the WFD, which requires member states to encourage active involvement of all interested parties in the production, implementation, review, and updating of the RBMPs (EC, 2003b). For each RBD, the public must have access to and be able to comment on: (1) a timetable and work programme for the production of the RBMP, including details of the consultation process, at least 3 years ahead of the starting date for the plan; (2) an initial overview of the significant water management issues identified in the RBD at least 2 years before the starting date for the plan; and (3) draft copies of the RBMP at least 1 year ahead of the starting date. Furthermore, on request the public should have access to background documents and information used in the preparation of the draft RBMPs and be given at least 6 months to submit written comments.

Assessment of progress and future challenges

Although broadly recognized as an ambitious and distinctive piece of EC legislation, the basis of the WFD and the detail of the implementation process have been subjects for critical discussion in the last decade. The ecological ideology underpinning the WFD, particularly the use of reference conditions to define ecological status, has been argued to be philosophically and pragmatically problematic because it fails to recognize humans as integral to, rather than external pressures on, ecosystems (Dufour and Piégay, 2009). While placing ecological principles at the heart of EC legislation is revolutionary, implementation of the WFD has focused strongly on traditional structural approaches to ecological

assessment (Basset, 2010). Consequently, the ecological potential of the WFD has failed to be realized, and important characteristics of ecological quality, including nutrient parsimony and connectivity between ecosystems, have not been incorporated in the implementation process (Moss, 2008). Identifying sites at reference condition in Europe is challenging, particularly for heavily human-impacted systems such as lowland rivers, and pristine sites that are considered as reference sites may actually have been significantly altered, for example, by atmospheric pollution (Hamilton et al., 2010). Impacts associated with future climate change may render reference conditions irrelevant, or require revision of these conditions during later cycles of the WFD (Noges et al., 2009). Distinguishing human impacts on an ecosystem from changes due to natural variability remains difficult (Hatton-Ellis, 2010) and is exacerbated by limited data records that do not enable natural variability to be characterized robustly. The cause of failure within a WB and the response of a WB to mitigation measures depend on complex, multivariate cause-effect relationships, and current understanding of these complex systems is often insufficient to support the ambitious aims of the WFD (Solimini et al., 2009). The timescale of the WFD has been argued to be overambitious. Complex ecosystems are unlikely to show clear responses to mitigation measures during the 6-year planning cycles of the WFD (Hering et al., 2010), and achieving default WFD objectives by 2015 in heavily impacted systems is unlikely to be feasible. The WFD has also been argued to require a fundamental shift in the spatial scale of assessment and restoration activities, moving away from site-specific work toward larger-scale activity (Hamilton et al., 2010). Although intuitively attractive, these larger-scale activities are difficult to realize in practice. Despite the intercalibration exercises undertaken as part of the WFD, significant and largely unexpected variation across Europe in reference conditions, water body typologies, assessment, and monitoring strategies has developed (Hering et al., 2010). While indicative of the greater flexibility offered by the WFD compared to previous EC legislation, some have argued that this variation reflects difficulties associated with the lack of precise definitions offered by the Directive (Moss, 2008).

In addition to the technical and scientific challenges presented by the WFD, significant institutional and administrative obstacles have to be overcome, not least in the 40 international river basins within the EU. According to the 2007 assessment conducted by the European Commission (EC, 2007), poor legal transposition and the lack of economic analysis are the biggest implementation gaps so far, but actions are also required by Member States with respect to the effectiveness of public participation and the integration of sustainable water management into other policy areas such as agriculture and urban development. The capacities of the designated CAs to implement all of the WFD requirements vary enormously, along with political commitment and funding made available for planning and the implementation of the programmes of measures. As a consequence, a north-south divide has

emerged, with many of the southern Member States falling behind the implementation timetable. Concern has also been expressed that some Member States have set extremely ambitious objectives and proposed measures without full consideration of relevant costs. It is highly likely that achievements by 2015 will vary widely across the EU, since Member States and their designated CAs have different starting points, different technical and administrative capacities, and different levels of ambitions expressed in their draft RBMPs (Water Information System for Europe, 2009).

Summary

The Water Framework Directive (WFD) is designed to provide an integrated approach to water resources management and protection for the whole of the European Union (EU). Through an iterative planning and implementation process, the Member States are required to designate river basin districts and appoint competent authorities with responsibility for the WFD, establish reference conditions for different types of water bodies, assess current conditions and identify appropriate objectives and programmes of measures to achieve them. This information is to be presented in the form of a river basin management plan for each designated district, and the planning process itself must make extensive use of both economic analysis and public participation. The first cycle of river basin management plans published in 2009 show considerable variation in approach and compliance with WFD requirements across the EU, with some Member States falling behind the implementation schedule and others setting ambitious environmental targets without adequate consideration of the likely economic costs.

WATER QUALITY FOR DRINKING: WHO GUIDELINES

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

Water for drinking comes from one or more of these sources. In order to satisfy the quality of the water being of acceptable standard, the World Health Organization (WHO), an agency of the United Nations Organization, has provided international *Guidelines for Drinking-water Quality*.

Diseases related to contamination of drinking water constitute a major burden on human health, the greatest majority of water-related health problems being the result of microbial contamination (bacteriological, viral, protozoan). In general terms the greatest microbial risks are associated with ingestion of water that is contaminated with human or animal feces. Feces can be a source of pathogenic bacteria, viruses, protozoa, and helminths.

In addition to fecally borne pathogens, other microbial hazards such as guinea worm, toxic cyanobacteria, and *Legionella* may also be important under specific circumstances.

The primary purpose of the *Guidelines for Drinking-water Quality* is the protection of public health.

Water is essential to sustain life, and a satisfactory (adequate, safe, and accessible) supply must be available to all. Improving access to safe drinking water can result in tangible benefits to health. Every effort should be made to achieve a drinking-water quality as safe as practicable.

Safe drinking water, as defined by the Guidelines, does not represent any significant risk to health over a lifetime of consumption, including different sensitivities that may occur between life stages. Those at greatest risk of water-borne disease are infants and young children, people who are debilitated or living under unsanitary conditions, and the elderly. Safe drinking water is suitable for all usual domestic purposes, including personal hygiene. The Guidelines are applicable to packaged water and ice intended for human consumption. However, water of higher quality may be required for some special purposes, such as renal dialysis and cleaning of contact lenses, or for certain purposes in food production and pharmaceutical use. Those who are severely immunocompromised may need to take additional steps, such as boiling drinking water, due to their susceptibility to organisms that would not normally be of concern through drinking water. The Guidelines may not be suitable for the protection of aquatic life or for some industries.

The Guidelines are intended to support the development and implementation of risk management strategies that will ensure the safety of drinking-water supplies through the control of hazardous constituents of water. These strategies may include national or regional standards developed from the scientific basis provided in the Guidelines. The Guidelines describe reasonable minimum requirements of safe practice to protect the health of consumers and/or derive numerical “guideline values” for:

Microbes in water

Although the greatest risk from microbes in water is associated with consumption of drinking water that is contaminated with human and animal excreta, other sources and routes of exposure may also be significant.

This chapter focuses on organisms for which there is evidence, from outbreak studies or from prospective studies in non-outbreak situations, of disease being caused by ingestion of drinking water, inhalation of droplets, or contact with drinking water, and their control.

Microbial hazards associated with drinking water

Infectious diseases caused by pathogenic bacteria, viruses, and parasites (e.g., protozoa and helminths) are the most common and widespread health risk associated with drinking water. The public health burden is determined by the severity of the illness(es) associated with pathogens, their infectivity, and the population exposed.

Breakdown in water supply safety may lead to large-scale contamination and potentially to detectable disease outbreaks. Other breakdowns and low-level, potentially repeated contamination may lead to significant sporadic disease, but is unlikely to be associated with the drinking-water source by public health surveillance.

Quantified risk assessment can assist in understanding and managing risks, especially those associated with sporadic disease.

Waterborne infections

The pathogens that may be transmitted through contaminated drinking water are diverse. Table 1 provides general information on pathogens that are of relevance for drinking-water supply management. The spectrum changes in response to variables such as increases in human and

animal populations, escalating use of wastewater, changes in lifestyles and medical interventions, population movement and travel, and selective pressures for new pathogens and mutants or recombinations of existing pathogens. The immunity of individuals also varies considerably, whether acquired by contact with a pathogen or influenced by such factors as age, sex, state of health, and living conditions.

For pathogens transmitted by the fecal-oral route, drinking water is only one vehicle of transmission. Contamination of food, hands, utensils, and clothing can also play a role, particularly when domestic sanitation and hygiene are poor. Improvements in the quality and availability of water, in excreta disposal, and in general hygiene are all important in reducing fecal-oral disease transmission.

Microbial water quality verification

For microbial water quality, verification is likely to include microbiological testing. In most cases, it will involve the analysis of fecal indicator microorganisms, but in some circumstances it may also include assessment of specific pathogen densities. Verification of the microbial quality of drinking water may be undertaken by the supplier, surveillance agencies, or a combination of the two.

Water Quality for Drinking: WHO Guidelines, Table 1 Waterborne pathogens and their significance in water supplies

Pathogen	Health significance	Persistence in water supplies	Resistance to chlorine	Relative infectivity	Important animal source
Bacteria					
<i>Burkholderia pseudomallei</i>	Low	May multiply	Low	Low	No
<i>Campylobacter jejuni</i> , <i>C. coli</i>	High	Moderate	Low	Moderate	Yes
<i>Escherichia coli</i> – pathogenic ^d	High	Moderate	Low	Low	Yes
<i>E. coli</i> – enterohaemorrhagic	High	Moderate	Low	High	Yes
<i>Legionella</i> spp.	High	Multiply	Low	Moderate	No
Nontuberculous mycobacteria	Low	Multiply	Low	Low	No
<i>Pseudomonas aeruginosa</i> ^e	Moderate	May multiply	Moderate	Low	No
<i>Salmonella typhi</i>	High	Moderate	Low	Low	No
Other salmonellae	High	May multiply	Low	Low	Yes
<i>Shigella</i> spp.	High	Short	Low	Moderate	No
<i>Vibrio cholerae</i>	High	Short	Low	Low	No
<i>Yersinia enterocolitica</i>	High	Long	Low	Low	Yes
Viruses					
Adenoviruses	High	Long	Moderate	High	No
Enteroviruses	High	Long	Moderate	High	No
Hepatitis A virus	High	Long	Moderate	High	No
Hepatitis E virus	High	Long	Moderate	High	Potentially
Noroviruses and sapoviruses	High	Long	Moderate	High	Potentially
Rotaviruses	High	Long	Moderate	High	No
Protozoa					
<i>Acanthamoeba</i> spp.	High	Long	High	High	No
<i>Cryptosporidium parvum</i>	High	Long	High	High	Yes
<i>Cyclospora cayentanensis</i>	High	Long	High	High	No
<i>Entamoeba histolytica</i>	High	Moderate	High	High	No
<i>Giardia intestinalis</i>	High	Moderate	High	High	Yes
<i>Naegleria fowleri</i>	High	May multiply ¹	High	High	No
<i>Toxoplasma gondii</i>	High	Long	High	High	Yes
Helminths					
<i>Dracunculus medinensis</i>	High	Moderate	Moderate	High	No
<i>Schistosoma</i> spp.	High	Short	Moderate	High	Yes

Approaches to verification include testing of source water, water immediately after treatment, and water in distribution systems of stored household water. Verification of the microbial quality of drinking water includes testing for *Escherichia coli* as an indicator of fecal pollution and should not be present in drinking water. In practice, testing for thermotolerant coliform bacteria can be an acceptable alternative in many circumstances. While *E. coli* is a useful indicator, it has limitations. Enteric viruses and protozoa are more resistant to disinfection; consequently, the absence of *E. coli* will not necessarily indicate freedom from these organisms. Under certain circumstances, it may be desirable to include more-resistant microorganisms, such as bacteriophages and/or bacterial spores. Such circumstances could include the use of source water known to be contaminated with enteric viruses and parasites or high levels of viral and parasitic diseases in the community.

Water quality can vary rapidly, and all systems are subject to occasional failure. For example, rainfall can greatly increase the levels of microbial contamination in source waters, and waterborne outbreaks often occur following rainfall.

Drinking-water safety is not related only to fecal contamination. Some organisms grow in piped water distribution systems (e.g., *Legionella*), whereas others occur in source waters (guinea worm) and may cause outbreaks and individual cases. Some other microbes (e.g., toxic cyanobacteria) require specific management approaches, which are covered elsewhere in these Guidelines.

Certain serious illnesses result from inhalation of water droplets (aerosols) in which the causative organisms have multiplied because of warm temperatures and the presence of nutrients. These include legionellosis and Legionnaires' disease, caused by *Legionella* spp.

Schistosomiasis (bilharziasis) is a major parasitic disease of tropical and subtropical regions that is transmitted when the larval stage (cercariae), which is released by infected aquatic snails, penetrates the skin. It is primarily spread by contact with water. Ready availability of safe drinking water contributes to disease prevention by reducing the need for contact with contaminated water resources – for example, when collecting water to carry to the home or when using water for bathing or laundry.

Other pathogens that may be naturally present in the environment may be able to cause disease in people with impaired local or general immune defense mechanisms, such as the elderly or the very young, patients with burns or extensive wounds, those undergoing immunosuppressive therapy, or those with acquired immunodeficiency syndrome (AIDS). If water used by such persons for drinking or bathing contains sufficient numbers of these organisms, they can produce various infections of the skin and the mucous membranes of the eye, ear, nose, and throat.

Most of the human pathogens listed in Table 1 are distributed worldwide; some, however, such as those causing outbreaks of cholera or guinea worm disease, are regional. Eradication of *D. medinensis* is a recognized target of the WHO.

It is likely that there are pathogens not shown in Table 1 that are also transmitted by water. This is because the number of known pathogens for which water is a transmission route continues to increase as new or previously unrecognized pathogens continue to be discovered.

Infectious disease caused by pathogenic bacteria, viruses, protozoa, and helminths are the most common widespread health risk with drinking water.

Persistence and growth in water

While typical waterborne pathogens are able to persist in drinking water, most do not grow or proliferate in water. Microorganisms like *E. coli* can accumulate in sediments and are mobilized when water flow increases.

After leaving the body of their host, most pathogens gradually lose viability and the ability to infect. The rate of decay is usually exponential, and a pathogen will become undetectable after a certain period. Pathogens with low persistence must rapidly find new hosts and are more likely to be spread by person-to-person contact or poor personal hygiene than by drinking water. Persistence is affected by several factors, of which temperature is the most important. Decay is usually faster at higher temperatures and may be mediated by the lethal effects of UV radiation in sunlight acting near the water surface.

The most common waterborne pathogens and parasites are those that have high infectivity and either can proliferate in water or possess high resistance to decay outside the body.

Public health aspects

Outbreaks of waterborne disease may affect large numbers of people, and the first priority in developing and applying controls on drinking-water quality should be the control of such outbreaks. Available evidences also suggest that drinking water can contribute to background disease in non-outbreak situations, and control of drinking-water quality should therefore also address waterborne disease in the general community.

Experience has shown that systems for the detection of waterborne disease outbreaks are typically inefficient in countries at all levels of socioeconomic development, and failure to detect outbreaks is not a guarantee that they do not occur; nor does it suggest that drinking water should necessarily be considered safe.

Some of the pathogens that are known to be transmitted through contaminated drinking water lead to severe and sometimes life-threatening disease. Examples include typhoid, cholera, infectious hepatitis (caused by hepatitis A virus [HAV] or HEV), and disease caused by *Shigella* spp. and *E. coli* O157. Others are typically associated with less-severe outcomes, such as self-limiting diarrheal disease (e.g., Norovirus, *Cryptosporidium*).

The effects of exposure to pathogens are not the same for all individuals or, as consequence, for all populations. Repeated exposure to a pathogen may be associated with a lower probability of severity of illness because

of the effects of acquired immunity. For some pathogens (e.g., HAV), immunity is lifelong, whereas for others (e.g., *Campylobacter*), the protective effects may be restricted to a few months to years. On the other hand, sensitive subgroups (e.g., the young, the elderly, pregnant women, and the immunocompromised) in the population may have a greater probability of illness, or the illness may be more severe, including mortality. Not all pathogens have greater effects in all sensitive subgroups.

Not all infected individuals will develop symptomatic disease (including carriers), which differs between pathogens and also depends on population characteristics, such as a prevalence of immunity.

To a large extent, people have no means of judging the safety of their drinking water themselves, but their attitude toward their drinking-water supply and their drinking-water suppliers will be affected to a considerable extent by the aspects of water quality that they are able to perceive with their own senses. It is natural for the consumers to regard with suspicion water that appears dirty or discolored or that has an unpleasant taste or smell, even though these characteristics may not in themselves be of direct consequence to health.

The provision of drinking water that is not only safe but also acceptable in appearance, taste, and odor is of high priority. Water that is aesthetically unacceptable will undermine the confidence of consumers, lead to complaints, and, more importantly, possibly lead to the use of water from sources that are less safe.

It is important to consider whether existing or proposed water treatment and distribution practices can affect the acceptability of drinking water. For example, a change in disinfection practice may generate an odorous compound such as trichloramine in the treated water. Other effects may be indirect, such as disturbance of internal pipe deposits and biofilms when changing between blending waters from different sources in distribution systems. The appearance, taste, and odor of drinking water should be acceptable to the consumer.

The WHO guidelines are applicable to large metropolitan and small community piped drinking-water systems and to non-piped drinking-water systems in communities and in individual dwellings. The guidelines are also applicable to a range of specific circumstances, including large buildings, travelers, and conveyances.

The great majority of evident water-related health problems are the result of microbial (bacteriological, viral, protozoan, or other biological) contamination. Nevertheless, an appreciable number of serious health concerns may occur as a result of the chemical contamination of drinking water.

Microbial aspects

Securing the microbial safety of drinking-water supplies is based on the use of multiple barriers, from catchment to consumer, to prevent the contamination of drinking water or to reduce contamination to levels not injurious to health. Safety is increased if multiple

barriers are in place, including protection of water resources, proper selection and operation of a series of treatment steps, and management of distribution systems (piped or otherwise) to maintain and protect treated-water quality. The preferred strategy is a management approach that places the primary emphasis on preventing or reducing the entry of pathogens into water sources and reducing reliance on treatment processes for removal of pathogens.

In general terms, the greatest microbial risks are associated with ingestion of water that is contaminated with human or animal (including bird) feces. Feces can be a source of pathogenic bacteria, viruses, protozoa, and helminths.

Failure to ensure drinking-water safety may expose the community to the risk of outbreaks of intestinal and other infectious diseases. Drinking-water-borne outbreaks are particularly to be avoided because of their capacity to result in the simultaneous infection of a large number of persons and potentially a high proportion of the community.

In addition to fecally borne pathogens, other microbial hazards (e.g., guinea worm [*Dracunculus medinensis*], toxic cyanobacteria, and *Legionella*) may be of public health importance under specific circumstances.

The infective stages of many helminths, such as parasitic roundworms and flatworms, can be transmitted to humans through drinking water. As a single mature larva or fertilized egg can cause infection, these should be absent from drinking water. However, the water route is relatively unimportant for helminth infection, except in the case of the guinea worm.

Legionella bacteria are ubiquitous in the environment and can proliferate at the higher temperatures experienced at times in piped drinking-water distribution systems and more commonly in hot and warm water distribution systems. Exposure to *Legionella* from drinking water is through inhalation and can be controlled through the implementation of basic water quality management measures in buildings and through the maintenance of disinfection residuals throughout the piped distribution system.

Public health concern regarding cyanobacteria relates to their potential to produce a variety of toxins, known as "cyanotoxins." In contrast to pathogenic bacteria, cyanobacteria do not proliferate within the human body after uptake; they proliferate only in the aquatic environment before intake. While the toxic peptides (e.g., microcystins) are usually contained within the cells and thus may be largely eliminated by filtration, toxic alkaloids such as cylindrospermopsin and neurotoxins are also released into the water and may break through filtration systems. Some microorganisms will grow as biofilms on surfaces in contact with water. With few exceptions, such as *Legionella*, most of these organisms do not cause illness in healthy persons, but they can cause nuisance through generation of tastes and odors or discoloration of drinking-water supplies.

Taste, odor, and appearance

Taste and odor can originate from natural inorganic and organic chemical contaminants and biological sources or processes (e.g., aquatic microorganisms), from contamination by synthetic chemicals, from corrosion, or as a result of water treatment (e.g., chlorination). Taste and odor may also develop during storage and distribution due to microbial activity.

Taste and odor in drinking water may be indicative of some form of pollution or of a malfunction during water treatment or distribution. It may therefore be an indication of the presence of potentially harmful substances. The cause should be investigated, and the appropriate health authorities should be consulted, particularly if there is a sudden or substantial change.

Color, cloudiness, particulate matter, and visible organisms may also be noticed by consumers and may create concerns about the quality and acceptability of a drinking-water supply.

Biologically derived contaminants

There are a number of diverse organisms that may have no public health significance but which are undesirable because they produce taste and odor. As well as affecting the acceptability of the water, they indicate that water treatment and/or the state of maintenance and repair of the distribution system are insufficient.

Actinomycetes and fungi

Actinomycetes and fungi can be abundant in surface water sources, including lakes and reservoirs, and they also can grow on unsuitable materials in the water supply distribution systems, such as rubber. They can give rise to geosmin, 2-methyl isoborneol, and other substances, resulting in objectionable tastes and odors in the drinking water.

Animal life

Invertebrate animals are naturally present in many water resources used as sources for the supply of drinking water and often infest shallow, open wells. Small numbers of invertebrates may also pass through water treatment works where the barriers to particulate matter are not completely effective and colonize the distribution system. Their motility may enable them and their larvae to penetrate filters at the treatment works and vents on storage reservoirs.

The types of animal concerned can be considered, for control purposes, as belonging to two groups. First, there are free-swimming organisms in the water itself or on water surfaces, such as the crustaceans (freshwater shrimp). Second, there are other animals that either move along surfaces or are anchored to them (e.g., water louse, snails, zebra mussel, other bivalve molluscs, and the bryozoan) or inhabit slimes (e.g., *Nais* spp., nematodes, and the larvae of chironomids). In warm weather, slow sand filters can sometimes discharge the larvae of gnats into the water.

Many of these animals can survive, deriving food from bacteria, algae, and protozoa in the water or present on

slimes on pipe and tank surfaces. Few, if any, water distribution systems are completely free of animals. However, the density and composition of animal populations vary widely, from heavy infestations, including readily visible species that are objectionable to consumers, to sparse occurrences of microscopic species.

Production of high-quality water, maintenance of chlorine residuals in the distribution system, and the regular cleaning of water mains by flushing or swabbing will usually control infestation.

Cyanobacteria and algae

Blooms of cyanobacteria and other algae in lakes and reservoirs and in river waters may impede coagulation and filtration, causing coloration and turbidity of water after filtration. They can also give rise to geosmin, 2-methyl isoborneol, and other chemicals, which have taste thresholds in drinking water of a few nanograms per liter. Some cyanobacterial products – cyanotoxins – are also of direct health significance.

Iron bacteria

In waters containing ferrous and manganous salts, oxidation by iron bacteria (or by exposure to air) may cause rust-colored deposits on the walls of tanks, pipes, and channels and carryover of deposits into the water.

Chemically derived contaminants

Aluminum

Naturally occurring aluminum as well as aluminum salts used as coagulants in drinking-water treatment are the most common sources of aluminum in drinking water.

Ammonia

The threshold odor concentration of ammonia at alkaline pH is approximately 1.5 mg/l, and a taste threshold of 35 mg/l has been proposed for the ammonium cation.

Chloride

High concentrations of chloride give a salty taste to water and beverages. Taste thresholds for the chloride anion depend on the associated cation and are in the range of 200–300 mg/l for sodium, potassium, and calcium chloride. Concentrations in excess of 250 mg/l are increasingly likely to be detected by taste, but some consumers may become accustomed to low levels of chloride-induced taste. No health-based guideline value is proposed for chloride in drinking water.

Chlorine

Most individuals are able to taste or smell chlorine in drinking water at concentrations well below 5 mg/l and some at levels as low as 0.3 mg/l.

Chlorophenols

Chlorophenols generally have very low taste and odor thresholds.

Color

Drinking water should ideally have no visible color. Color in drinking water is usually due to the presence of colored organic matter (primarily humic and fulvic acids) associated with the humus fraction of soil. Color is also strongly influenced by the presence of iron and other metals, either as natural impurities or as corrosion products. It may also result from the contamination of the water source with industrial effluents and may be the first indication of a hazardous situation. The source of color in a drinking-water supply should be investigated, particularly if a substantial change has taken place.

Copper

Copper in a drinking-water supply usually arises from the corrosive action of water leaching copper from copper pipes.

Dissolved oxygen

The dissolved oxygen content of water is influenced by the source, raw water temperature, treatment, and chemical or biological processes taking place in the distribution system. Depletion of dissolved oxygen in water supplies can encourage the microbial reduction of nitrate to nitrite and sulfate to sulfide. It can also cause an increase in the concentration of ferrous iron in solution, with subsequent discoloration at the tap when the water is aerated. No health-based guideline value is recommended.

Hardness

Hardness caused by calcium and magnesium is usually indicated by precipitation of soap scum and the need for excess use of soap to achieve cleaning. Public acceptability of the degree of hardness of water may vary considerably from one community to another, depending on local conditions. In particular, consumers are likely to notice changes in hardness.

The taste threshold for the calcium ion is in the range of 100–300 mg/l, depending on the associated anion, and the taste threshold for magnesium is probably lower than that for calcium. In some instances, consumers tolerate water hardness in excess of 500 mg/l.

Depending on the interaction of other factors such as pH and alkalinity, water with a hardness above approximately 200 mg/l may cause scale deposition in the treatment works, distribution system and pipework, and tanks within buildings. It will also result in excessive soap consumption and subsequent “scum” formation. On heating, hard waters form deposits of calcium carbonate scale. Soft water, with a hardness of less than 100 mg/l, may, on the other hand, have a low buffering capacity and so be more corrosive for water pipes.

Hydrogen sulfide

The taste and odor thresholds of hydrogen sulfide in water are estimated to be between 0.05 and 0.1 mg/l. The “rotten eggs” odor of hydrogen sulfide is particularly noticeable in some groundwaters and in stagnant drinking water in

the distribution system, as a result of oxygen depletion and the subsequent reduction of sulfate by bacterial activity.

Iron

Anaerobic ground water may contain ferrous iron at concentrations of up to several milligrams per liter without discoloration or turbidity in the water when directly pumped from a well. On exposure to the atmosphere, however, the ferrous iron oxidizes to ferric iron, giving an objectionable reddish-brown color to the water.

Manganese

At levels exceeding 0.1 mg/l, manganese in water supplies causes an undesirable taste in beverages and stains sanitary ware and laundry. The presence of manganese in drinking water, like that of iron, may lead to the accumulation of deposits in the distribution system.

Monochloramine

Most individuals are able to taste or smell monochloramine, generated from the reaction of chlorine with ammonia, in drinking water at concentrations well below 5 mg/l and some at levels as low as 0.3 mg/l.

pH and corrosion

Although pH usually has no direct impact on consumers, it is one of the most important operational water quality parameters. Careful attention to pH control is necessary at all stages of water treatment to ensure satisfactory water clarification and disinfection. For effective disinfection with chlorine, the pH should preferably be less than 8; however, lower-pH water is likely to be corrosive. The pH of the water entering the distribution system must be controlled to minimize the corrosion of water mains and pipes in household water systems.

Sulfate

The presence of sulfate in drinking water can cause noticeable taste, and very high levels might cause a laxative effect in unaccustomed consumers. Taste impairment varies with the nature of the associated cation; taste thresholds have been found to range from 250 mg/l for sodium sulfate to 1,000 mg/l for calcium sulfate. It is generally considered that taste impairment is minimal at levels below 250 mg/l. No health-based guideline value has been derived for sulfate.

Total dissolved solids

The palatability of water with a TDS level of less than 600 mg/l is generally considered to be good; drinking water becomes significantly and increasingly unpalatable at TDS levels greater than about 1,000 mg/l.

Turbidity

Turbidity in drinking water is caused by particulate matter that may be present from source water as a consequence of

inadequate filtration or from resuspension of sediment in the distribution system. It may also be due to the presence of inorganic particulate matter in some groundwaters or sloughing of biofilm within the distribution system. The appearance of water with a turbidity of less than 5 NTU is usually acceptable to consumers, although this may vary with local circumstances.

Temperature

Cool water is generally more palatable than warm water, and temperature will impact on the acceptability of a number of other inorganic constituents and chemical contaminants that may affect taste. High water temperature enhances the growth of microorganisms and may increase taste, odor, color, and corrosion problems.

Chemical water quality

Assessment of the adequacy of the chemical quality of drinking water relies on comparison of the results of water quality analysis with guideline values.

For additives (i.e., chemicals deriving primarily from materials and chemicals used in the production and distribution of drinking water), emphasis is placed on the direct control of the quality of these products. In controlling drinking-water additives, testing procedures typically assess the contribution of the additive to drinking water and take account of variations over time in deriving a value that can be compared with the guideline value.

Most chemicals are of concern only with long-term exposure; however, some hazardous chemicals that occur in drinking water are of concern because of effects arising from sequences of exposures over a short period. Where the concentration of the chemical of interest varies widely, even a series of analytical results may fail to fully identify and describe the public health risk (e.g., nitrate, which is associated with methemoglobinemia in bottle-fed infants). In controlling such hazards, attention must be given to both knowledge of causal factors such as fertilizer use in agriculture and trends in detected concentrations, since these will indicate whether a significant problem may arise in the future. Other hazards may arise intermittently, often associated with seasonal activity or seasonal conditions. One example is the occurrence of blooms of toxic cyanobacteria in surface water.

A *guideline value* represents the concentration of a constituent that does not exceed tolerable risk to the health of the consumer over a lifetime of consumption. Guidelines for some chemical contaminants (e.g., lead, nitrate) are set to be protective for susceptible subpopulations. These guidelines are also protective of the general population over a lifetime.

Bacterial pathogens

Most bacterial pathogens potentially transmitted by water infect the gastrointestinal tract and are excreted in the feces of infected humans and other animals. However, there are also some waterborne bacterial pathogens, such

as *Legionella*, *Burkholderia pseudomallei*, and atypical mycobacteria, that can grow in water and soil. The routes of transmission of these bacteria include inhalation and contact (bathing), with infections occurring in the respiratory tract, in skin lesions, or in the brain. A list of these is shown in the following table (Table 2).

Assessing microbial priorities

The most common and widespread health risk associated with drinking water is microbial contamination, the consequences of which mean that its control must always be of paramount importance. Priority needs to be given to improving and developing the drinking-water supplies that represent the greatest public health risk.

Water Quality for Drinking: WHO Guidelines,
Table 2 Pathogens in drinking water

Bacterial pathogens	Acinetobacter Aeromonas Bacillus Burkholderia pseudomallei Campylobacter Escherichia coli pathogenic strains Helicobacter Klebsiella Legionella Mycobacterium Pseudomonas Salmonella Shigella Staphylococcus aureus Tsukamurella Vibrio Yersinia
Viral pathogens	Adenoviruses Astroviruses Caliciviruses Hepatitis A virus Hepatitis E virus Rotaviruses and orthoreoviruses
Protozoan pathogens	Acanthamoeba Balantidium coli Cryptosporidium Cyclospora cayetanensis Entamoeba histolytica Giardia intestinalis Isospora belli Microsporidia Naegleria fowleri Toxoplasma gondii
Helminth pathogens	Dracunculus medinensis Fasciola spp.
Toxic cyanobacteria	
Indicator and index organisms	Total coliform bacteria Escherichia coli and thermotolerant and coliform bacteria Heterotrophic plate counts Intestinal enterococci Clostridium perfringens Coliphages Bacteroides fragilis phages Enteric viruses

Microbial contamination of major urban systems has the potential to cause large outbreaks of waterborne disease. Ensuring quality in such systems is therefore a priority. Nevertheless, the majority (around 80%) of the global population without access to improved drinking-water supplies reside in rural areas. Similarly, small and community supplies in most countries contribute disproportionately to overall drinking-water quality concerns. Identifying local and national priorities should take factors such as these into accounts.

Assessing chemical priorities

Not all of the chemicals with guideline values will be present in all water supplies or, indeed, all countries. If they do exist, they may not be found at all levels of concern. Conversely, some chemicals without guideline values or not addressed in the WHO guidelines may nevertheless be of legitimate local concern under special circumstances.

Only a few chemicals have been shown to cause widespread health effects in humans as a consequence of exposure through drinking water when they are present in excessive quantities. These include fluoride, arsenic, and nitrate. Human health effects have also been demonstrated in some areas associated with lead (from domestic plumbing), and there is concern because of the potential extent of exposure to selenium and uranium in some areas at concentrations of human health significance.

WATER QUALITY IN LAKES AND RESERVOIRS

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Introduction

Pure water does not exist in nature. There are a wide range of factors which can be used to define water quality that no simple definition exists. Water which is of excellent quality for certain purposes may be totally unsuitable for other purposes. However, the overall quality of the aquatic environment of lakes and reservoirs can only be fully described in terms of hydrology, physicochemistry, and biology. Changes in oxygen, pH, carbon dioxide, and other variables are often substantial during a 24 h period due to the influence of solar radiation on temperature and photosynthesis. There are therefore seasonal differences in water quality due to the impact on biological

processes of differing lengths of daylight, temperature, and other factors.

Precipitation whether in the form of rain, snow, or ice washes gases and dust particles out of the atmosphere. The gases include oxygen, carbon dioxide, ammonia, and iron from industrial sources, sulfur dioxide, carbon monoxide, oxides of nitrogen, and hydrocarbons. Rainfall has always been slightly acidic due to the natural formation of carbonic acid which has become more acidic today due to the formation of nitric and sulfuric acids as a result of industrial pollution. The rain collects impurities while passing through the air and further changes in quality take place as a result of the twin processes of erosion and solution. Thus, the composition of water in lakes and reservoirs in terms of both dissolved and suspended matter closely reflects the geology of the catchment or basin. Such differences can have major influences on the aquatic flora and fauna of the catchment.

Rivers collect impurities from the earth and through the discharge of sewage and industrial effluents and these are carried to lakes and reservoirs. All surface waters must be regarded as potentially polluted although natural purification occurs in large lakes and reservoirs through sedimentation and the death of pathogenic bacteria. Water from these may frequently show no bacterial evidence of past contamination. The water quality characteristics of lakes and reservoirs are therefore variable and depend on many factors.

Storage in reservoirs

Water storage in reservoirs modifies the wide variation in water quality.

Bacterial concentrations in reservoirs are reduced as a result of the unfavorable bacteriological environment coupled with a long detention period. Turbidity is decreased by sedimentation of suspended particles in the relative quiescence of the impoundment. The bleaching action of sunlight is responsible for removing color from water retained in the reservoir. However, effects of impoundment may exhibit objectionable tastes and odors, high color, objectionable algal growth, low concentrations of dissolved oxygen, and high concentrations of iron, manganese, and hydrogen sulfide. All these, undesirable on water quality, are due largely to thermal stratification of reservoirs during certain periods of the year. Storage or residence time in lakes may range from weeks to hundreds of years.

Thermal stratification

Deep reservoirs can be expected to develop thermal stratification during the warm periods. The Spring warming of the surface waters creates thermal density differences between the deep water which has been stored through the preceding winter and the warmer low density water near the surface. This temperature gradient results in a stable stratification which resists mixing by wind and other forces.

Normally, an intermediate layer of maximum temperature gradient (the *thermocline*), forms between an upper

layer (the *epilimnion*), and the deep layer (the *hypolimnion*).

The thermocline in natural lakes is often observed in depths of 10 m or more below the surface but in reservoirs may be less depending on withdrawal rates.

Water above the thermocline in the epilimnion is stirred by wind and wave action which combines with photosynthesis of algae to maintain dissolved oxygen in the water at near saturation levels. Below the thermocline, however, little mixing occurs and sunlight, necessary for photosynthesis, does not penetrate to the hypolimnion. The stagnant water, deprived of reaeration cannot replenish the dissolved oxygen which is consumed by biochemical processes.

These processes gradually reduce the dissolved oxygen to levels significantly below saturation level and frequently exhaust it completely. The same biologically processes which utilize the oxygen, produce carbon dioxide resulting in the production of acidic conditions.

The quality of water in the hypolimnion becomes progressively worse until late summer or autumn. Cooler weather lowers the temperature of the surface water, increasing its density, so that it sinks and mixes with the deeper water in the hypolimnion. Eventually, all the water in a reservoir becomes of relatively uniform temperature and density.

In climates of warm temperature, reservoir water will remain mixed throughout its depth and well aerated during cooler periods. In cooler latitudes, however, deep reservoirs exhibit winter stratification resulting from cooling of the surface waters to below 4°C. the point of maximum density. Colder but less dense water will remain on the surface of the reservoir, with bottom water temperature at about 4°C. If ice-cover forms, wind disturbance ceases and the reservoir may become stagnant and spring will bring on warmer air temperatures and start the stratification cycle again.

Impurities in water

Impurities in water may be in solution or in suspension. Although poisonous metals such as lead may occasionally be found in natural waters, dissolved impurities are not usually harmful, but, if present in excessive quantities, they make the water undesirably hard or unsuitable for domestic and some industrial uses.

Upland reservoirs are usually of good bacterial quality on account of their situation and the protection often afforded to the gathering grounds. However in other areas, reservoirs may be affected by bacteria from excremental pollution such as types of *Escherichia coli*, *Citrobacter freundii*, *Klebsiella aerogenes*, and *E. cloacae* (*Enterobacter cloacae*).

Diseases of bacterial origin

Diseases of bacterial origin associated with water from reservoirs if not satisfactorily treated are:

1. Typhoid
2. Paratyphoid

3. Cholera
4. Dysentery (bacillary and amoebic)
5. Gastroenteritis
6. Weil's disease (Leptospirosis jaundice)

Measurement of water quality in lakes and reservoirs

Temperature

Temperature is a key characteristic of all water bodies because it influences physical, chemical, and biological processes. Lakes and reservoirs exhibit both seasonal and diurnal variations in temperature which may be related to climate and geographic location. Shallow lakes may have a uniform temperature from top to bottom, but deep lakes may become stratified.

Temperature is always measured in situ at the time of sampling by means of a thermometer or thermistor.

Transparency

Transparency is a useful guide to biological productivity and is measured in the field usually from a boat by lowering a white circular disk 200 to 300 mm in diameter (known as a Secchi disk) on a graduated cable and observing the depth at which it disappears from sight. It is then slowly raised and the depth at which it reappears is noted. The mean of these two depths is the depth of transparency.

The transparency of natural waters can vary substantially in Europe usually from 0.5 to 15 m, but values of 50 m have been observed in some crater lakes and values of 20–25 m have been observed in European alpine lakes.

Color

The true color of a sample of lake water can only be measured in the laboratory after filtration. The true color is measured after filtration either visually or by a photoelectric method.

Turbidity

Turbidity in lakes arises from the scattering of light by suspended solids. Turbidity measurements are of particular interest to managers of water treatment works as a quick and simple guide to water quality.

Suspended solids

Almost all surface waters contain suspended particulate matter which is derived from natural weathering in the catchment.

Suspended solids by settling out on the lake or reservoir bed can be harmful to bottom living organisms and prevent the breeding of fish by stopping the free flow of oxygenated water through the gravel in which the fish lay their eggs. Total suspended solids (TSS) are determined in the laboratory by passing the water sample through a special filter. TSS is one of the most variable of water quality characteristics.

Total dissolved solids

Total dissolved solids (TDS) are determined by passing a measured volume of the sample through a filter of small pore size and evaporating the filtrate in an evaporating dish.

Conductivity

Electrical conductivity provides a simple way of estimating the concentration of dissolved organic salts. The method is particularly useful in reservoirs of potential sources of drinking water. The test is best carried out in the field using a conductivity meter. It is measured in Siemens per meter or in millisiemens per meter. The values found in most natural lakes are in the range 5–50 mS/m but may rise to 100 or more in mineralized waters and in very polluted waters could rise to 1,000 mS/m.

pH

The pH scale is a convenient way of measuring the acidity or alkalinity of a sample of lake water. The scale extends from 0 (extremely acid) to 14 (extremely alkaline), while the midpoint pH7 corresponds to exact neutrality. In natural lake water, pH is controlled by the relationship, or equilibrium, among carbon dioxide, bicarbonate, and carbonate ions, and can be strongly influenced by biological activity. Thus, photosynthesis by algae and other plants during daylight hours utilizes carbon dioxide and the pH may rise sharply, while by night the main biological activity is respiration which produces carbon dioxide and the pH decreases accordingly.

The natural pH of rain is around 5.6, but industrial emissions of sulfur dioxide together with oxides of nitrogen from industry and transport lead to the formation of sulfuric and nitric acids so that rainfall has become much more acid during the last century average values ranging from 4 to 5 in Europe. Some waters are naturally acidic in mountain areas due to humic acids, but not as acidic as those affected by industrial acidification. In some circumstances in lakes a total loss of fish life can occur.

Chemical characteristics

The chemical components of natural waters in lakes can be grouped in five categories: particulate; inorganic substances; dissolved inorganic substances, and dissolved gases.

Particulate inorganic substances, the main source of minerals which carried in suspension by streams in the catchment, are the mechanical erosion of rocks and soils brought about by wind, running water, frost, ice movement, and land slips. In lakes, particulate matter is also derived from biochemical processes such as photosynthesis which cause the precipitation of calcium from solution as calcite (calcium carbonate).

Dissolved inorganic substances

As soon as rain falls on the earth's surface, it starts to dissolve minerals according to the acidity or alkalinity of the water, the relative solubilities of the minerals and other factors.

Rainwater contains many ions in solution, and of these sodium, potassium, calcium, magnesium, and chloride are derived mainly from particles in the atmosphere, while sulfate, ammonium, and nitrate ions are derived mainly from atmospheric gases. It is estimated that about 54% of the rain falling on the earth's surface is evaporated, leaving 46% as runoff so that the concentration of ions in river water is over double that derived from rainwater. Most of the dissolved inorganic material in rivers and lakes originates from the weathering of rocks and soil and from man-made sources. It is estimated that in some countries 10–15% of calcium, sodium, and chloride comes from rainfall in contrast to about one quarter of the potassium and half of the sulfate.

Major ions

Sodium

Sodium is one of the most abundant elements in the earth's crust and is present in all natural waters. In surface water the natural concentrations is usually below 10 mg/l and rarely above 50 mg/l. Analysis is normally carried out by atomic emission spectrophotometry.

Potassium

Concentration of potassium is generally low in lakes except in agricultural areas where fertilizers may give high levels. Analysis is carried out by atomic emission spectrophotometry.

Calcium

Calcium is widely distributed in surface rocks, usually in the form of carbonate or sulfate, for example, limestone chalk and gypsum. Natural lake water usually contains less than 15 mg/l.

Calcium and magnesium which are invariably present together are responsible for hardness in water which can be defined as the ability of the water to precipitate calcium and magnesium salts of fatty acids from soap solution. Analysis is by titration with ethylenediamine (EDTA).

Magnesium

Magnesium is an essential element for living organisms and universally present in natural waters. Concentrations in lake water are usually in the range 1–100 mg/l.

Analysis is by titration with EDTA or by atomic absorption spectrophotometry.

Carbonates and bicarbonates

All natural waters contain in solution carbon dioxide, carbonic acid, carbonate, and bicarbonate ions in a buffered system which is important to the health of the aquatic flora and fauna. Carbon dioxide is derived from the atmosphere by absorption at the air–water interface from the respiration of aquatic organisms and from the bacterial decomposition of organic matter either in suspension or in the bottom sediments. The weathering of rocks contributes carbonate and bicarbonate salts. In areas of non-carbonate

geology, the carbonate, and bicarbonate is entirely derived from the atmosphere and biogenic carbon dioxide.

Photosynthesis plays a major role in the precipitation of calcium carbonate in lakes and in very pure waters the results of acid rain may seriously depress the pH to 4.5 or less resulting in the death of fish eggs and fry. The deaths may not be directly caused by the acidity but by toxic metal aluminum leached from the soil under acid conditions.

Concentrations of carbonate, bicarbonate, and carbon dioxide are usually calculated from measurements of the pH (by glass electrode), alkalinity (by titration), temperature, and ionic strength.

Sulfate

Sulfate is highly soluble and widely distributed in surface rocks and easily leached from gypsum (calcium sulfate). Levels in lakes may have concentrations in the range 1–80 mg/l although pollution from industrial sources may result in much higher levels. Natural hot spring waters may contain several thousand mg/l.

Analysis may be carried out by gravimetric determination of barium sulfate after ignition or by EGTA titration.

Chloride

Chloride is universally present in freshwaters derived from weathering of sedimentary rocks and rain. The average concentration in rivers and lakes may be under 10 mg/l, but high levels can occur due to pollution or industrial inputs. Lakes in coastal areas may have very high concentrations. Chloride is chemically and biologically unreactive and samples may be stored at room temperature. Analysis is by titration with silver nitrate or directly with chloride sensitive electrodes.

Minor ions

Minor ions: nitrate, phosphate, and silicate are of vital importance in aquatic ecosystems as nutrients for plant growth and particularly in the growth of phytoplankton and may limit productivity at low concentrations while high levels may cause undesirably high growths of macrophytic plants and algae.

Nitrogen

Nitrogen is essential for all living organisms as a major constituent of protein and genetic material such as DNA. Bacteria and plants utilize inorganic nitrogen from the water to produce organic matter such as protein within their cells while animals such as zooplankton and fish derive their protein from plants. When these organisms die, a range of microorganisms convert organic compounds, such as the various proteins, to ammonia and eventually to gaseous nitrous oxide and elemental nitrogen. These transformations form part of the nitrogen cycle found in terrestrial eco-systems.

In lakes nitrogen is present as nitrate at concentrations of about 0.1 mg/l as nitrate nitrogen. Levels of ammonia and of nitrite are usually below 0.1 mg/l because nitrifying bacteria ensure that any residue is oxidized to nitrate.

Phosphorus

Like nitrogen, phosphorus is an essential element for plant growth, being a constituent of protein, phospholipids, and nucleic acids. It is present in lakes in the form of orthophosphate, polyphosphate, and organically bound phosphates. In lakes phosphorus is normally found in the range from 0.005 to 0.02 mg/l but may be much higher if pollution is present. Analysis is by filtration. Results are reported in terms of phosphate phosphorus.

Silicate

After oxygen, silicon is the most abundant element in the earth's crust and a major constituent of igneous and metamorphic rocks, clays, feldspars, and quartz. It is believed that dissolved silica in lakes is derived from the chemical weathering of aluminum silicates by complex processes. The measurement is usually by as the oxide, silica, the concentration lying between 1 and 30 mg/l but may be as much as 1,000 mg/l in brackish lakes.

Analysis is by the calorimetric method using plastic containers to prevent leaching of silicate from glass.

Trace inorganics

The trace metals found almost universally in lakes are: iron, copper, cobalt, boron, manganese, molybdenum, zinc and aluminum. These are important as micronutrients with concentrations of between one nanogram and one microgram per liter.

Chemical analysis at these levels requires specialized trained staff with absorption spectrometry and electrothermal atomization or other instrumentation.

Particulate organic substances

Particulate organic matter in lakes includes living microscopic organisms such as phytoplankton, zooplankton, and bacteria, dead organisms, breakdown material of decaying leaves and large animals, windblown pollen and seeds. Particulate organic matter is measured as particulate organic carbon (POC) by a variety of methods, all of which are based on the oxidation of the carbon in the sample after filtration and drying to carbon dioxide. The oxidation is performed by combustion and the carbon dioxide produced measured using a specific electrode or other means.

Dissolved organic substances

These are derived from the breakdown of solid organic matter by natural biological processes some of which may take place within the lake and are measured as dissolved organic carbon (DOC).

In most lakes DOC comprises the greater part of the total organic carbon and is in the range 1–20 mg/l. Total organic carbon (TOC) is determined without filtration.

Gases in solution

Oxygen and nitrogen dissolve in water in different proportions from those in the atmosphere. However because it is chemically inert, nitrogen is not important in water quality

in lakes. In water quality aspects, the important gases are therefore oxygen and carbon dioxide. Oxygen is vital to all living organisms and because only small amounts are present in water even under saturated conditions, the concentration of dissolved oxygen is a key measure of the health of lake water. In lakes, dissolved oxygen can show marked diurnal and seasonal variation especially under eutrophic conditions. In strong sunlight in summer, the surface layers of lakes may become supersaturated with oxygen concentrations of 150–200%, while during darkness, respiration of the plankton may reduce the dissolved oxygen to saturation values of 50–80%. In extremely eutrophic lakes especially with pollution present, the dissolved oxygen concentrations may decrease to near zero, thus causing fish deaths.

Carbon dioxide

While air contains about 21% oxygen and only about 0.03% carbon dioxide, the higher solubility of the latter means that its relative concentration in water is proportionally higher. Since carbon dioxide reacts with water to produce carbonic acid, the equilibrium between the various components is highly complex.

In eutrophic lakes with abundant phytoplankton, photosynthesis in daylight depresses the carbon dioxide while oxygen is substantially increased and because of its relationship with carbon dioxide, the pH can rise significantly. The reverse takes place at night when carbon dioxide increases, the pH drops, and oxygen decreases.

Hardness

Hardness is the term used in the water industry for describing the suitability of water for domestic and industrial purposes. Hard water contains high concentrations of calcium and magnesium salts such as bicarbonates, sulfates and chlorides which are precipitated from solution by soap and by heating. Natural hard waters are typically found in areas of calcareous sedimentary rocks such as chalk and limestone while soft waters occur in areas of basic or metamorphic rocks such as granite and slates. Hardness is of importance in that it influences the toxicity of many heavy metals such as copper and lead to aquatic organisms but otherwise is not a particularly useful term for describing the quality of waters in lakes.

WETLAND AREAS AND LAKES IN BULGARIA

Reginald W. Herschy¹, George Gergov (Deceased)

¹Hydrology Consultant, Reading, UK

Introduction

“Wetland areas” as an independent category of natural water sites are very often omitted in the formulation of the subject of hydrological activities. These areas comprise lakes and marshes, water reservoirs of total depth below 6 m, coastal strips, and other sites of stagnant water or high humidity level.

Definition of wetland areas

These areas have characteristics, which have not been adequately studied by the contemporary environmental science since it would require the combined efforts of specialists from different research fields, including ecology, chemistry, hydrology, engineering sciences, economic sciences, etc. For this reason, the different specialists deal with different definitions, which is a natural outcome of the fields of their specific interests and research methodology.

Wetland areas are part of the natural environment characterized by permanent presence of water. The influence of the water cycle on the wetland areas is most often connected with changes in their water regime during the different hydrologic seasons. They are multifunctional sites, which provide very often human settlements with drinking water and water for industrial applications, serve as locations for angling and sources for irrigation purposes, act as buffers against floods and as tailing reservoirs for urban and industrial wastewater, serve as transport ways or sources for power generation, and, last but not least, they are indispensable for wild life and plants. Sometimes, they are called “nature’s kidneys” because of their function in the hydrological and chemical cycle. They clean contaminated waters. They feed the ground water-bearing layers. They are also often called “biological supermarkets” because of the rich biodiversity available in them.

Different professionals – geologists, soil scientists, hydrologists, biologists, ecologists, sociologists, economists, specialists in political sciences, medical doctors, and jurists give different definitions, which is a natural

consequence of their different spheres of interest, the educational background of the providers of the definition and the different way in which they treat these areas. They rank among the most significant ecosystems on the Earth and are a valuable source, host and transformer of a great multitude of chemical, biological, and genetic materials. Many of them produce large quantities of their own organic matter, which may have a strong impact on water quality by changing even its color or increasing the value of the chemically required oxygen (CRO). Maltby et al. (1998) systematize the functions and impacts of wetland areas on other spheres of natural environment and society, thus highlighting their great importance for science and the social practice.

From the conducted study of literature sources, it has become evident that there is no satisfactory and generally recognized definition of the natural sites known under the name “wetland areas.” The definition that enjoys the broadest popularity is that of the Ramsar Convention (Ramsar Convention on Wetlands, 1990) concerning wetland areas of international significance. According to it, wetland areas are natural sites, which comprise “swamps, peat-bogs and natural or manmade, permanent or temporary water areas of static or running fresh, slightly salty and salty water, including areas filled by sea water, whose ebbing depth is below 6 m.”

Natural wetland areas

At the beginning of the twentieth century in Bulgaria, there were 200,000 ha of natural lakes and marshes. The first large-scale efforts for reclamation of marshland areas were launched in the 1920s with the Straldga Marshland. From a modern environmental point of view it is, however, a rough assault on the largest and one of the richest marshlands in Bulgaria. Afterward, the appetites turned to the next biggest swamp – the Karaboaz Marshland, drained by the end of the 1930s. The objective was to allot the land reclaimed from nature as arable land to emigrants from Aegean Thracia and Asia Minor. Interventions of this kind used to be conducted during the same period in the river Sruma and river Mesta estuaries in Greece, which indicates that reclamation used to be a mass practice in some European countries in the early twentieth century.

In the sense of that above formulation, a large number of wetland areas had existed in Bulgaria by the end of World War II – marshlands along the low-lying banks of the river Danube, along the stretches of many tributaries of the Danube River in the Black Sea coastal area and in the Thacian Lowlands. Illustrated on [Figure 1](#) is a scheme of the distribution of the significant natural and technogenic wetland areas in the country (Report..., 2000).

After World War II the liquidation of marches, above all along the Danube River banks, acquired mass scale with the motivation to combat mosquitoes and malaria, as well as to reclaim new arable land, which had been distributed among the poor inhabitants for tilling.

Wetland Areas and Lakes in Bulgaria, Figure 1 Scheme of the distribution of natural and man-made wetland areas in Bulgaria.

Within a brief period of time almost all marshes along the Danube River, with the exception of Srebarna, Malak Preslavets, and Garvan, had been drained (refer to Table 1).

The Mandreshko Lake and Rabishko Lake have been converted into reservoirs by dams. The same fate has befallen the Batak Marshland in the Rhodopes Mountains after the construction of a large dam on its location. At the same time, embankments and riverbed correction facilities have been built along the stretches of the feeder river to prevent the overflow of its water over its banks. In this way within short time, the desired positive drainage effect has been achieved, accompanied by lasting changes in the topography of the locality, the vegetation cover of the affected areas, and the local ecology. The drainage facilities have ensured retention of the high runoff waves and their accumulation for the purposes of irrigation and combating floods (Gergov, 1963). These interventions have, however, destructed the routes for natural supply of the wetland areas with nutrient substances and river sediments, which endangers their existence. The larger wetland areas in still active state in Bulgaria are listed in Table 2.

River training works have been made, which have destructed almost all the existing meanders. As a result only a small portion of the natural wetland areas has been preserved in Bulgaria, whereas almost all of them have been influenced by human activities.

The study and preservation of wetland areas in Bulgaria has started at the beginning of the last century with a detailed description of the vegetation and animal species in the Straldga Marshland (Yokimov, 1909). Another

study of this kind on vegetation in marshes was conducted by Yordanov (1931). Striburni (1930) has described the Karaboaz Marshland and Petrov (1961) – the Srebarna Lake. An in-depth survey of the wetland areas in Bulgaria was made by Kochev and Yordanov (1981). A complete literary survey and detailed study of the algae-flora of the Bulgarian Danubean coastline and the adjacent basins have been conducted by Draganov and Staneva (1992), of the zoo-plankton – by Naydenov (1984) etc. Ivanov et al., (1961) have compiled a complete hydrographic directory and hydrological description of natural lakes in Bulgaria by means of maps, schemes, sectional views, and other forms of useful information. This publication contains part of the collected information about the quality of water there, the zoobenthos, biocenosis, aqua species, and other

ecosystems, as well as the issues related to their conservation as nature sites.

The existent currents and pollution of the Bourgas Bay have been detected by means of two detailed nature "snapshots" taken in the course of two consecutive expeditions conducted in 1986 and 1988 (Gergov et al., 1990), immediately after the Chernobyl incident. During calm, anticyclone weather, cyclone-type circulation current has been

detected (Figure 2), extending over the entire aquifer of the Bourgas Bay and causing long-lasting retention (up to 18 days) of pollution generated by the city of Bourgas and its industrial zone. This phenomenon causes deterioration of the quality characteristics of the beaches and presents a potential health risk for the holiday-makers in this area. The speed of the currents is quite low – up to 15–16 cm/s.

Their existence has been corroborated through analysis of satellite photos of the area and through conducting of densitometric analysis (Mishev et al., 1982). Reference to other investigations of this kind is made in an article devoted to the currents in the area of the hydrological complex Varna Bay – adjacent lakes (Vesselinov and Gergov, 1980).

The first natural wetland area placed under the protection of the Law on Nature Protection was the river Ropotamo, declared in 1940 as a nature reserve. Proposals for two more natural wetland areas – the Srebarna and Arkutino reserves – were put forward together with the document for incorporation of the Ropotamo nature reserve in the list of sites covered by the Convention on Wetland Areas. In 1984, two more reserves were added to the list of Bulgarian sites – Atanasovsko Lake and the Durankulak Nature Landmark. The four sites account for a total area of 2,097 ha. Bulgaria joined also the Regina Convention of 1987 by virtue of Decision No. 76/1990 of the Bureau of the Council of Ministers and in this way the state began to fulfill its financial and protection-related obligations ensuing from it. In connection with the implementation of the Convention in 1994, a new integrated National Plan concerning priority actions for conservation of the 88 most significant wetland areas was developed. This plan distinguishes between three groups of wetland areas.

- Drained marshes – 12
- Existing lakes and marches in natural condition – 51
- Dams – 22

Listed in Table 3 are the priority natural wetland areas according to the National Plan, divided into three groups: wetland areas of global significance, wetland areas of continental significance, and wetland areas of national significance.

Man-made wetland areas

For the purposes of this study, a review is made of the category on man-made wetland areas such as artificially created ground pits, filled permanently or temporarily with stagnant water, irrespective of the depth of the water layer up to maximum 6 m. The lifting of this limitation as to the water depth allows us to extend the coverage of the studies to all the dams and micro-dams constructed in the country. Moreover, the areas along the banks of the big dams have all the features and characteristics of wetland areas – small depth, slow currents, higher temperature of the water environment, contacts with polluters, and other agents of anthropogenic origin. They contribute to regulation of

Wetland Areas and Lakes in Bulgaria, Figure 2 Currents in the aquifer of the Bourgas Bay in anti-cyclone weather (Gergov et al., 1990).

defused pollution coming from the neighboring agricultural areas, deposition of sediment matter, transformation of the biogenic elements and their biological, photochemical, and mechanical disintegration, reduction of soil erosion, and under certain circumstances prevention of flooding of the areas situated at lower levels. The existence of dams enriches the landscape, creates new conditions for recreation, sports, and business activities, and contributes to the development of natural habitat for many plant and animal species. In the literature, these kind of artificial lakes are generally called “man-made wetland areas” (Yokimov, 1909). The man-made wetland areas are particularly important for the maintenance of the water

ecosystems, for improvement of the quality of water through self-purification, etc.

Regretfully, however, the operation and protection of this kind of wetland areas are not clearly regulated in the national legislation and in the European directives concerning water and water facilities. There exist a relatively small number of rules and legally established standards and documents related to their implementation.

The majority of the smaller dams (approx. 2,000) are multifunctional, used mainly for irrigation, as fish-breeding and recreation facilities, while the bigger dams ($>10.10^6 \text{ m}^3$) are used mainly for energy generation and water supply.

To insure good functioning the dams require protection of their internal hydrological system and water circulation, which are often distorted or neglected because of the insufficient or entirely missing knowledge about their management on part of their owners. The period of transition of Bulgarian agriculture through privatization has had a grave impact on many water sites because of the failure of the state to set up a regulatory framework for their safe and environmentally sound operation, maintenance, and protection.

Dams in Bulgaria

A total of 2,040 dams with a summary storage capacity of 7.773 billion cubic meters (refer to Table 4) are in situ in the country for regulation of the seasonal and multi-annual water runoff. The degree of runoff regulation achieved in this way is about 39%, ensuring approximately 920 m³/inhabitant. Their major hydrographic and water economy characteristics are systematized in several publications (Nikolova, 2000; Report, 2000; Gergov and Varbanov, 2002).

The experience accumulated in Bulgaria has revealed that dams with a storage capacity above five million cubic meters (a total of 91 with a summary storage capacity amounting to 7.036 billion cubic meters or 90.5% of the total installed storage capacity of all reservoirs) have a great importance for development of water economy activities and for meeting the water demands of the country. The remaining 1,949 dams feature storage capacity below five million cubic meters and are predominantly of local importance and therefore do not play a decisive role for the sustainability of the national water economy balance.

Aerial distribution of the dams in terms of their storage capacity

The aerial distribution of this type of wetland areas is of great significance for meeting the demand of drinking water and water for other different applications, like irrigation and power generation. Bulgarian rivers are not

navigable because of their variable hydrological regime. There exist, however, certain preserved memoirs and monastery chronics, which tell that till the end of the Middle Ages cargo barges and rafts used to sail along the lower stretches of the rivers Struma, Maritsa, and Iskar, carrying, timber goods and livestock from the inland to the Arabian markets. This information may be assumed as evidence for the high water-bearing capacity of the

region, formed by the climate during that period, and the overall spread of natural forest areas.

The dams for irrigation purposes enjoy the broadest distribution. The majority of them are situated along the river courses as follows: along the Maritsa River – about 665, Tundga – 245, Yantra – 181, Kamchiya – 121, etc. The largest number of big dams (storage capacity above five million cubic meters) exists along the courses of the Maritsa River (24), Kamchiya (9), Struma and Yantra (7 each), Iskar (6) and Tundga (5).

The constructed dams allow high degree of regulation of the river discharges thanks to their available storage capacities. For the main rivers in Bulgaria, these are as follows: river Maritsa – 1.599 billion cubic meters, river Arda – 1.269 billion cubic meters, river Kamchiya – 0.978 billion cubic meters, river Iskar – 0.814 billion cubic meters, and river Ogosta – 0.585 billion cubic meters. The dam storage capacities in situ along the border rivers (Nishava, Erma, Veleka) and some of the rivers discharging in the Black Sea (Devnya, Dvoynitsa, Fakiyska etc.) are insignificant. Their small annual runoff might be subjected to higher degree of regulation through construction of small dams or redistribution of their runoff across the area.

Distribution of dams in terms of designation

According to their designation the dams may be divided into the following groups:

- Dams of complex designation
- Dams for irrigation purposes
- Dams for energy generation
- Dams for drinking water supply
- Dams for industrial water supply
- Dams for fish-breeding
- Retention storage capacities and dams of special designation

The complex dams belong to the sites of national significance and for that reason their management involves more complicated principles of subordination – neither sector-based alone, nor territorial alone. There are a total of 30 such dams, featuring total storage capacity of 3.1 billion cubic meters (Table 4), which accounts for 40% of the summary installed storage capacity in the country. These dams are of exclusive importance for meeting the drinking water demand. Their share is the biggest along the river Maritsa (the so-called Rila-Rhodopes cascades), comprising five complex dams of 0.67 billion cubic meters total storage capacity, followed by that along the river Iskar – four dams, total storage capacity 0.54 billion cubic meters and the river Ogosta – three dams, storage capacity 0.51 billion cubic meters.

The total storage capacity of regulated water, which is used for *irrigation* purposes, is about two billion cubic meters (25% of the total capacity). The largest number of dams for irrigation purposes exists along the river valleys possessing favorable conditions for agricultural irrigation.

- River Maritsa 650 dams with a total storage capacity 0.714 billion cubic meters
- River Tundga 242 dams with a total storage capacity 0.15 billion cubic meters
- River Yantra 161 dams with a total storage capacity 0.144 billion cubic meters
- River Kamchiya 113 dams with a total storage capacity 0.414 billion cubic meters
- River Vit 58 dams with a total storage capacity 0.105 billion cubic meters

The small dams (below five million cubic meters) have multiple applications in agriculture – for irrigation, stock-rearing, fish-breeding, etc. – at relatively low costs and minimum maintenance requirements. Unfortunately, the construction of the reservoirs had not been based on adequate design, construction methods, and maintenance provisions, specific for that type of facilities (Stoychev et al., 1988). On the other hand, these are small facilities, which do not require any particular care and maintenance during their short life cycle. The use of local materials for their construction gives their users the self-confidence that this is light and insignificant construction effort.

Mass distribution has been noted for *micro-dams* (below one million cubic meters storage capacity), which are spread all over the country. Some of them have been converted into recreation areas. Almost all of them have been constructed with funding allocated by the Ministry of Agriculture from the Regional Territorial Development Fund or Mitigation of Erosion Fund, however at the national level there is no summary information about them at all.

There is a total of ten water supply dams with a total storage capacity of about 0.5 billion cubic meters, the biggest ones being those on the rivers Yantra, Kamchiya, and Iskar.

The number of dams used specifically for *power generation* is small – a total of nine with a total storage capacity of 1.173 billion cubic meters, which account for approximately 15% of the total storage capacity of dams in the Republic of Bulgaria. Their regulation capacity is considerable. A number of dams, which have originally been built for power generation, have later shifted to the group of complex ones, since the development of the area had put forward the requirement for priority meeting of other types of water demand. In perspective there are no plans for construction of dams specifically for power generation with the exception of the Gorna Arda Cascade. Famous big dams for power generation applications in the country are Iskar, the Batak Cascade, Vacha Cascade, Topolnitsa, Koprinka, Al. Stamboliyski, Petrokhan etc.

Dams for water supply applications are in situ at many places throughout the country. The better known among them are Yasna Polyana, Hristo Smirnovski, Tsonevo, Srechenska Bara, Beli Iskar, Dyakovo, etc. The dams for industrial water supply with conventionally clean water are also only a few (14) and of insignificant storage capacities – 0.294 billion cubic meters or 4.4% of the total volume of the water reservoirs.

There are about 20 water reservoirs for fish breeding in situ in the country. Their storage capacity is insignificant – 0.4% of the total. There are also 21 dams for struggle against floods (retention capacities) and special purpose dams, whose storage capacity is also insignificant (0.2% of the total). In recent years, as a consequence of the transfer of the small irrigation dams under the control of municipalities, or their privatization, or yet their lending for operation and management under concession agreements, they are used predominantly for fish breeding.

The fish-breeding ponds are usually built on the location of former lakes, marshes, and quagmires, some of the more famous among them being those at the village of Orsoya, the village of Mechka, the village of Nova Cherna, the village of Karaysen (Veliko Tarnovo District), the city of Byala, the city of Rousse, the village of Chelopechene, Sokolitsa, the city of Blagoevgrad, the city of Plovdiv, etc.

Quarry lakes have been formed as a consequence of the extraction of clay, gravel, sand, or coal. They are used most frequently as retention storage capacities for irrigation, water supply for agriculture, stock-rearing, etc. These are some of the water facilities, which have a variety of negative impacts on the environment (Yurdanov and Gergov, 1996).

Rice fields occupy relatively vast areas around the cities of Pazardgik, Plovdiv, and Stara Zagora. Their intensive cultivation is connected with increased impact on the water resources and the environment in these regions.

The period before the passing of the Law on Local Self-government and Local Administration, at the offset of the economic reforms in the Republic of Bulgaria, was characterized by two types of ownership on the dams: state and cooperative. Cooperative ownership extended over 1,847 dams of summary storage capacity of 0.533 billion cubic meters. State ownership is split and comprises 166 hydro-ameliorative and complex dams of a total storage capacity of 2.527 billion cubic meters.

After the promulgation of the Law on Local Self-government and Local Administration, a process of transformation of the ownership on the small dams had started. However, sometimes after its enforcement the launching of the agrarian reform triggered a new problem the absence of criteria for identification of the ownership rights on them and the inadequacy in their management, which might lead to their ruins.

These are engineering facilities implemented by means of local building materials, without adequate technical supervision of their state and operation (Stoychev et al., 1988). They meet local needs, such as irrigation of vegetable gardens, fish-breeding, stock-rearing farms, sports, and entertainment. In certain cases, they feed water to small irrigation-bound fields. The design of the small dams has been made practically in the absence of reliable hydrological data because there were no hydrometric stations installed on the brooklets and small rivers. For this reason, empirical data and improper methodologies were usually used for that purpose and consequently these

facilities bear the risk of unforeseen averages in the event of formation of torrential floods. There is no information with respect to the sediment load influx in the small dams either and hence the process of blocking up with slime of some of them develops at a surprisingly high pace. This situation reduces their utilization and increases the risk of their overflow in floods, which might result in partial or full demolition of the dams. Danger might emerge any-time if unauthorized actions were undertaken, such as building of superstructure on the dam, or filling in of the spillway, or blocking of the drain cocks with the aim to retain more water in the reservoir. Overflowing of dams might lead to their destruction, which is a potential danger for the nearby human settlements. Conducting of periodical control surveys and measurements for assessment of the technical state-of-repair of the small dams is necessary, however in actual fact this is not done regularly and at the required competence level.

The practice with respect to the operation of small dams reveals a number of omissions and inappropriate activities in the field of maintenance and management, including absence of any hydrometric measurements of the water balance components, the sediment load and sludge building, the quality of water and the sources of pollution, the absence of wastewater treatment facilities at the stock-rearing farms, etc.

Grave environmental problems, affecting the life and health of the human beings, the ecosystems and the environment in general, are created also by the tailing reservoirs, which are in fact water storage facilities of specific designation. Irrespective of their formal compatibility with lakes in terms of morphological properties, they are man-made facilities entirely deprived of life because of the high concentration of pollutants as a result of ore floatation, coal rinsing, technological processes in industry, etc. Averages happening in these facilities, however, have a grave effect on the river environment, the sanitary conditions in the human settlements and all the biocenoses in the host-river. Such a case of negative consequences as a result of the partial destruction of the tailing reservoir at the Maritsa I TPP in the city of Galabovo on the river Sazliyka in 1991 has been studied in detail by the author (Gergov, 1993) – [Photo 1](#), including its development up to the border with Turkey at Svilengrad.

The author has assessed the concentration of pollutants, their distribution, and sedimentation in the riverbed, the speed of their spread along the river network and their gradual dilution. In certain cases, like the one described above, the average might cause also claims from abroad for pollution of trans-border water currents. The above-described case may serve as an example for the negative consequences that might emerge in the event of average of small dams, provided no preventive care is taken.

Some years ago at the decision of a State Commission with the Council of Ministers, a profound technical audit of all such dams was implemented. The results from that audit reveal the following:

Wetland Areas and Lakes in Bulgaria, Photo 1 Destruction of the tail lake at the Galabovo town in 1991.

- Five hundred and twenty-six dams are in a poor technical state-of-repair and in bad need of comprehensive rehabilitation and repair works.
- Ninety-two dams are subject to decommissioning because of their grave damage and hence costly rehabilitation works. This number comprises also 15 potentially dangerous dams.

Another major type of wetland areas spread in the country is undoubtedly that of the river islands. The majority of those situated in the inland rivers are of movable sand-gravel islands, that is, they originate from temporary deposited bottom sediments – [Photo 2](#).

During the periods of low flow some of them become objects of biological stabilization through ample growth of moisture-loving vegetation – grass, bushes, and trees (Raynov et al., 1980). This development converts the temporary piling of river sand and gravel into long-lasting river morphological formation. They undergo periodical changes of their outlines and their height, even full washing away during high water, since they are built of riverbed materials (loose bulk sand and gravel) (Pechinov et al., 1979; Gergov and Nenov, 1984). Economic utilization of some of these islands ([Photo 2](#)) is possible thanks to their long-standing existence. This includes their intensive use as pastures, for timber logging, development of sports and angling facilities, construction of attraction facilities etc. The largest number of islands, however, exists along the Danube River stretches in the Bulgarian section – a total of 147 (Gergov and Nenov, 1984). Some of them are of “river terrace” origin and represent large earth masses of fine deposited material. They have almost unchanging outline as different from movable sediments islands.

River-based sand and gravel quarries – modern modalities of wetland areas

The boom in housing and road construction requires large quantities of sand and gravel. Traditionally, the cheapest method for their provision is their extraction from the riverbeds, where they have been deposited. These raw materials are greatly preferred because of the easy access to them. One major requirement for the setting up of efficient quarry enterprises along the rivers is the availability of large quantities of renewable deposits of sediment load from the river ([Photo 3](#)).

When the productivity of the river bed pits takes into account these deposits, their artificial extraction causes mainly reversible distortions of the riverbed and does not affect gravely the sediment depositions in the river or on its planned and depth-related forms. When, however, the abstraction of sand and gravel from the rivers exceeds the capacity of the river course to recover these, it might cause irreversible distortions of the riverbed at considerable distance above and below the location of the ballast quarry (Kosturkov, 1975; Nenov, 1984) etc.

At many locations the digging of sand and gravel from the riverbeds is performed outside the riverbed on depths, which exceed several times the depth of the river. Some of them occupy dozens of ha of washed away soil and humus cover. The conducted observations reveal that in many cases they are very dangerous deep-water spots for many decades, without any rehabilitation once the operators have left the quarry ([Photo 2](#)). In such cases, mainly ground water fills them and creates standing water mirror, which leads to eutrophication ([Photo 4](#)), followed by gradual filling by vegetation residues and materials from

Wetland Areas and Lakes in Bulgaria, Photo 2 Movable sand-gravel island in the Maritza River near the town of Harmanly.

Wetland Areas and Lakes in Bulgaria, Photo 3 Pilling of the flooded river terrace on the river Malki Iskar at the village of Svode.

crumbling down, the spread of wetland trees and bushes, and creation of a specific micro-climate.

Similar processes develop also in the “tails” of the tailing reservoirs, such as those along the Struma River at the village of Lobosh or at the Koprinka Dam, etc. (Gergov et al., 1983; Gergov and Ninov, 1986).

Five hydrological aspects

Hydrological aspects are assigned an important role in the study of wetland areas. These comprise: typification and

classification, working out the water balance of the affected areas, influx of sediment materials and nutrients; water currents; water pollution.

The practice of operation of the big dams shows that because of the high water losses due to evaporation and feeding the ground water supplies for the purposes of maintaining the water balance, it is necessary to set up hydrometric points at several points along the banks of the water mirror (Gergov, 1974). The hydrological information collected at these points allows accurate

Wetland Areas and Lakes in Bulgaria, Photo 4 Initial eutrophication of a deserted river bed pit in the river Topolnitsa basin.

determination and regulation of the water balance components and, wherever necessary – efficient use and protection of water resources. Such requirements are in force with respect to wetland areas as well, since in their case it is very difficult to identify the feeder province, the exact boundaries of the site and its interaction with natural sites of a similar kind.

The second important direction of hydrological investigations of wetland areas is related to the sediment load transported by the river courses, since they form part of the trophic chains of water species, and their deposition on the bottom contributes to the siltation of the lake and formation of biotope of water ecosystems. It is the depositing of the sediment matter that makes possible the rapid growth of torfaceous vegetation (Gergov, 1996, 2001; Gergov and Karagyozyova, 2002). Some scientists pay special attention to it because of its role as mediator of pollution (Report, Koprinka dam, 1991).

River sediments have, on one hand, mechanical action, which ensues from their depositing on the bottom and lasting accumulation in wetland areas (Gergov, 1989, 2001 and others). The sedimentation of these materials diminishes the water volume in the wetland area and that is a hindrance to the further water exchange in it. A special study on the Lessichevo water reservoir has been conducted (Report Lessichevo, 2000) (Photo 5). The test samples taken from the lake in situ and proper measurements have revealed the following:

- The charging of the water reservoir with sediment matter has developed rapidly and has resulted in complete filling in of its free capacity. This has led to diminishing of its efficiency and opportunities for practical use.

- The grave pollution of the river influx coming from the water catchment with toxic substances and heavy metals from the Medet-Assarel mining has led to accumulation of large quantities of arsenic, copper, etc. on the bottom, which endanger the further use of the water reservoir for irrigation purposes.

Alternatively, the absence of currents creates favorable conditions for intensive deposition of sediment matter and the development of torfaceous vegetation, which hinders still graver the penetration of fresh water and the emergence of putrefactive processes. In order to prevent such development, it is necessary to set up and maintain water flow there by means of human intervention. This is called forth by the requirement to maintain good conditions for development of the ecosystems and limitation of the eventual development of organisms causing diseases.

In several subsequent investigations of the same bay – detailed on-site measurements and remote sensing measurements, densitometric analysis of photo snaps and analyses of spatial images of the area (Petkova and Gergov, 1983) have corroborated this result. Moreover, it has been found out that at the outlet of the bay there is a current oriented southwards, which runs close to the coastline and can visually be tracked down to the region of the city of Sozopol. These findings are of environmental significance and might serve to help identify the sources of pollution and the mechanism of their distribution across this important holiday making and economic area. Rousenov and Stanev (1986) have worked out also a mathematical model of the currents in the bay.

The very first investigation in Bulgaria of the water currents in a large wetland area – the Beloslavsko Lake and

Wetland Areas and Lakes in Bulgaria, Photo 5 The Lessichevo water reservoir is clogged and overgrown with water vegetation.

Wetland Areas and Lakes in Bulgaria, Figure 3 Currents in the Lake-Bay hydro-complex near the city of Varna.

the Varna Bay (Vesselinov and Gergov, 1980; Gergov, 1989) by means of a number of automatic sea propellers type “A.Ott.Kempton” – has revealed the scheme of the currents in this water complex (Figure 3). This has permitted to determine the route of penetration of pollution from the industrial area of the city of Varna, from Devnya and Provadiya, to the city beach on the Varna Bay, to Galata and other beach strips. It has been found that industrially polluted water from the industrial zone of the city of Varna, mixed with stagnant fresh water in the Beloslavsko Lake, enriched with organic contaminants products from the ongoing putrefactive processes there, discharges in the area of the Varna Bay and causes pollution of the

coastal strip and the nearby situated city beach with pollutants of different types and in different concentrations. At the same time, a large portion of the transported sediment load is deposited in the southern end of the bay and forms an underwater sand bank right opposite the entry to the navigation canals, which creates situations of risk for the ships entering the large industrial port from the sea. On the other hand, the salty sea waters rush in the direction of the lakes along the southern canal as a counter current. In this way an intensive intermixture of fresh and seawaters, charged with pollution of different composition and transmitting nutrient environment of different composition. Later investigations have revealed that the above-indicated

Wetland Areas and Lakes in Bulgaria, Figure 4 Distribution of the bottom-level sediments in Koprinka Dam depending on the grain size of sediment particles (Gergov, 1991, 1992).

scheme is dynamic and depends on the meteorological situation and the state of water volume in the lake.

Similar measurements of the currents in Koprinka lake were conducted by means of improved submerging floaters at different water horizons (Report Koprinka, 1991). The results obtained through direct high-depth measurements cast ample light on the underwater local depositions of fine sediment sludge featuring variable granulometric composition in the cup of the dam (Gergov, 1992) (Figure 4).

Anthropogenic impact on wetland areas

The study of the wetland areas involves specific attention to the conducting of engineering activities in the respective region – road building, water abstraction, building of embankments, etc. This is due to the fact that the lessons learned from the past decades have highlighted the fact that the results are negative when a one-sided approach is applied for resolution of the problems, without good knowledge of the possible consequences. One example in this respect is the river Kamchiya mouth in Bulgaria, famous for its vast and beautiful flooded terrace oak forest – Longoza (Raynov et al., 1980). The annual overflows of the river have created full-value wetland area

featuring rich living environment – oak forests, lianas and climbing plants, moor vegetation, a thick layer of rotting dead foliage, and abundance of wild life. The correction of the riverbed in this section has resulted in limitation and even complete abolishment of overflows, which has created a threat to the existence of the rich vegetation diversity. The supply of fresh water, river sediments, and nutrients from the river to the terrace has been cut off. The straight-line shift of the river route has led to increase of the slope of water current and hence of its transport capacity, as a result of which a process of river degradation has begun, involving gradual washing away of the beach strip in the river Kamchiya mouth area and hence reduction of the size of the sediment “torch” opposite it. In this way it has become possible to excavate building components of an ancient port that had existed on that location (Raynov et al. 1974). The negative consequences from the described engineering activities on the state and dimensions of the wetland areas make it urgently necessary to consider the possibility for restoration of the natural equilibrium and full restoration of the famous unique wetland area Longoza through liquidation of all the elements of human intervention in its existence.

Back to nature

In the course of time, the attitude toward wetland areas in the country has changed. Presently, there is a general awareness of their ecological role for maintaining the rich biodiversity. Thanks to the efforts of environmental NGOs, the idea to protect and recover these wetland areas and lakes and revive their role as regulators of natural processes following the example of Great Britain, the USA, Russia, etc., has taken more definite shape.

Conclusions

The above brief presentation of the problems and peculiarities of natural and man-made wetland areas in the country has revealed that they are part of the total national water resources. The political and economic changes that have taken place in the recent years and the latest amendments to the environmental protection legislation of the country require adequate changes in the attitude toward protection of water resources and development of a national strategy for their sustainable and safe use, more specifically the following:

1. All types of wetland areas (natural, man-made, inland, coastal, fresh or salt water ones, etc.) possess unique characteristics, which are not adequately highlighted by the contemporary ecological science.
2. The investigations of the wetland areas require interdisciplinary approach.
3. There is a growing interest in and a drive to the formulation of a stable policy for regulation and management of all types of wetland areas, which calls for the establishment of a sustainable research and information framework, integrated in the form of a strategy for development and conservation of the wetland areas.

The main issues pending resolution with respect to the management of wetland areas comprise prevention of environmental pollution, eutrophication and threat to biodiversity. This gives rise to socioeconomical and legislative issues related to the use and preservation of their resources, the role of the state, local authorities and the individual water end-users in this process etc.

WETLANDS

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

Wetlands cover a large part of the Earth perhaps of the order of 6% or 1.8 million km² and may be termed habitats between dry land and deep water including marshes,

swamps, peatland, bogs, rivers, streams, ponds, and lakes. Estuaries, coastal waters, salt marshes, mangroves, and coral reefs may also be classified as wetlands. It is estimated that some 75% of the world's population live in former wetlands and surrounding areas. Wetlands are always in a state of change as lakes and ponds dry up or fill with plants or as salt marshes or mangrove swamps gradually extend out to sea.

Wetlands of international importance now include nearly 2,000 sites (known as Ramsar Sites – the Convention on Wetlands). The nation with the most sites is the UK with 168, but the nation with the greatest area of listed wetlands is Canada with over 130,000 km². The world's largest wetland is the Pantanal which straddles Brazil, Bolivia, and Paraguay in South America with Kakadu National Park in Australia not far behind. Scotland contains over 10,500 km² of blanket bog, and the "flow country" there, at some 4,000 km², is probably the largest single expanse of blanket bog in the world.

The Ramsar convention

The Ramsar Convention is an international treaty for the conservation and sustainability of wetlands, their scientific, economical, cultural, and recreational value to the community. The name is from the city of Ramsar in Iran and founded in Ramsar by participating nations there in 1971.

According to the Wildfowl and Wetlands Trust (WWT), half of the world's wetlands have already been lost over the last century, and this is increasing. WWT engages and inspires people, governments, and businesses to take direct action to save wetlands and their wildlife and encourages the creation of wetland centers worldwide.

Reedbeds and fens

In the UK, for example, key reedbeds and fen areas include the Tay estuary, the Norfolk and Suffolk Broads, and Far Ings along the Humber Estuary.

Transboundary Ramsar sites

Transboundary Ramsar Sites (TRS) may extend across national borders, and the Ramsar site authorities on both or all sides of the border have formally agreed to collaborate in its management.

The Ramsar list

The Ramsar List is an official product of the Ramsar Convention on Wetlands and is maintained by the treaty secretariat in collaboration with Wetlands International.

The list is continually updated with every new site added and arranged alphabetically. The list shows the site name, date of designation, region within the country, surface area in hectares, and central geographical coordinates of each site. An annotated Ramsar List is available as a 500-page spiral-bound publication with a paragraph of amplification of each Ramsar site (ramsar@ramsar.org).

Wetlands purification systems

Wetlands may serve as wastewater purification systems where satisfactory dissolved oxygen can be obtained by spreading the wastewater over wetlands. Such examples are in Calcutta and Arcata in California.

Note: The study of wetlands has recently been termed *paludology* in some publications.

WETLANDS OF THE CANADIAN ARCTIC

Ming-ko Woo¹, Kathy Young²

¹School of Geography and Earth Sciences, McMaster University, Hamilton, ON, Canada

²Department of Geography, York University, Toronto, ON, Canada

Introduction

The Canadian Arctic is an area north of the treeline. With an area of 2.7 million km², it occupies about one-quarter of the total land area of Canada. Wetlands cover about 3–5% of the Arctic, mostly in the south. Despite their limited extent, they provide an important ecological niche for plants, migratory birds, and animals of the far North. Wetlands can be a sink for atmospheric and terrestrial contaminants; and persistently flooded and high groundwater level in wetlands with carbon-rich soils can give rise to methane production. Arctic wetlands also sequester carbon in the water column, their underlying substrate muds, and through long-term peat accumulation and storage. Drainage leads to the loss of wetlands and disturbance to the peatland can accelerate peat decomposition to release its stored carbon while the removal of peat as an insulator enhances permafrost degradation.

The Canadian Arctic

The Arctic has a harsh climate, with winters that span 9–10 months when mean January air temperature falls below –15°C. In polar regions, solar radiation input is extremely uneven during the year. With up to 24 h of darkness and intense coldness, there is a net radiation loss in several winter months, but in summer, the low level of radiation flux is compensated by long daylight hours. Precipitation is low, usually below 250 mm per year. Only mountainous areas have annual precipitation exceeding 500 mm. Most of the precipitation comes as snow, and with a long cold season, the snow can accumulate to considerable amounts when spring melt arrives. Arctic wetlands benefit from meltwater supply and from frequent fog and low clouds that deposit trace rainfall (0.2 mm per 6-h period) in summer.

Persistent low temperatures are transmitted to the ground to foster the development of permafrost (defined as bedrock, organic or earth material with temperatures at or below 0°C persisting over at least two consecutive summers). Permafrost, when rich in ground ice, tends to be impervious to water flow. Permafrost terrain has a special suite of geomorphic features including patterned grounds, frost cracks and ice-wedge polygons, ice-cored mounds of various dimensions, and thermokarst terrain caused by melting of ground ice in the permafrost followed by land subsidence and surface erosion. All these attributes have an effect on wetland hydrology.

The Canadian Arctic encompasses a range of topography, from coastal plains and deltas to rolling hills of the Canadian Shield and undulating relief of the Arctic Lowland, to rugged mountains of Eastern Arctic ([Figure 1](#)). Topography influences water storage and movement, thus affecting wetland formation. Flat terrain facilitates water stagnation and inundation, rolling topography gives rise to depressions to collect lateral drainage, but steep slopes allow easy drainage. The land surface of the Arctic is largely barren in the High Arctic, and wetlands offer isolated patches with more vegetation than their surrounding polar desert.

Vegetation increases in density and diversity from the High to the Low Arctic. Mats of algae (normally blue-green spp.) are common in both saline and freshwater pond substrates. Wetland vegetation comprises largely mosses and herbaceous plants. *Sphagnum* moss occurs prevalently, as do sedges (*Carex* spp.), cotton grass (*Eriophorum* spp.), and graminoids. Drier tops of sedge hummocks and pond rims typically give rise to Arctic Willow (*Salix arctica*), Arctic Avens (*Dryas integrifolia*), Arctic Poppy (*Papaver radicum*), and a variety of *Saxifraga* spp., *Draba* spp., and Lousewort (*Pedicularis* spp.). Lichen ground cover is minimal in High Arctic wetlands (Woo and Young, 2003) but can be found frequently in the Low Arctic where they usually coexist with moss and peat. Toward the southern fringes of the Low Arctic, shrubs (*Betula* spp. and taller *Salix* spp.) and Ericaceous shrubs such as Labrador Tea (*Ledum palustre*) and Blueberry (*Vaccinium uliginosum*) become increasingly luxurious.

Wetlands of the Canadian Arctic, Figure 1 (top) Physiographic regions of Canadian Arctic. (bottom) Southern limit of the Arctic and zones of marine transgression and regression.

Occurrence of wetlands

A wetland is defined as “lands saturated for most parts of the growing season to allow the development of hydric soils, or support of hydrophytes or prolonged flooding up to a depth of 2 m” (National Wetlands Working Group, 1988). The occurrence of wetlands is affected by three major factors:

1. *Climate*: An excess of precipitation over evaporation will ensure ample water supply to a wetland. Despite low precipitation of the Arctic, evaporation rate is restricted by low supply of energy so that wetlands are found in this semi-arid environment where inputs from lateral sources provide adequate water to maintain wetlands.
2. *Topography*: Depressions and low-lying areas collect and store water, while areas of low gradient have

sluggish flow and retain water for protracted periods to sustain wetlands. Wetlands are found on steep terrain only where local water supply is ample, such as below melting snowbanks and in front of glaciers.

3. *Soil*: Most Arctic wetlands are underlain by peat which has high capacity to retain moisture. Within or below the peat layer is perennially frozen soil which prevents vertical water loss to percolation, allowing the water table to stay close to the surface.

Wetlands are a hydrological feature, and as such, a hydrology-related classification scheme is most appropriate. The Canadian wetland classification system recognizes several types of wetlands: bogs, fens, marshes, swamps, and shallow open waters. Hydrological interpretation can be attached to each wetland type.

1. Bogs obtain moisture mainly from the atmosphere (rain, snow, fog) and shed water to its surroundings. They are thus poor in nutrients.
2. Fens receive lateral drainage from surface and subsurface sources in addition to atmospheric water. They generally have a high water table and are supplied with nutrients from their adjacent lands.
3. Marshes and swamps occur in areas subject to lateral inundation for various durations by rivers, lakes, or the sea. They have standing water or gentle flow conditions. Swamps are distinguished from marshes by the growth of trees and luxuriant shrubs. Since Arctic wetlands lie above the treeline, swamps are not part of the consideration.
4. Ponds are shallow water bodies arbitrarily distinguished from lakes on the basis of water depth. Their depth in the summer never reaches 2 m, and the pond water usually freezes to the bottom in winter.

An Arctic wetland can belong to one of the above categories, or it is a combination of two or more of the wetland types. Thus, the lower part of a fen may merge with a marsh that is inundated by a lake, or a bog can coexist with a fen in different parts of a wetland.

Arctic wetlands

Arctic wetlands occur as isolated patches with areas of 1–10 km², or they cover extensive areas from the meso-scale (10–100 km²) to the regional scale (>100 km²). Patchy wetlands are particularly common in the High Arctic. Extensive wetlands are commonly encountered on low-lying plains.

Patchy wetlands

Based on hydrogeomorphology, Woo and Young (2003) recognized several types of patchy wetlands based mainly on their position in the landscape and their water source which includes snowmelt, groundwater, surface runoff, and inundation by freshwater (rivers and lakes) or the sea. Figure 2 is a conceptualization of occurrence of patchy wetlands in the Arctic.

Wetlands below snowbanks

Deep snowbanks are built up on hillslopes by long periods of snow drifting in the winter. A snowbank can become semi-permanent if not completely ablated in one summer. Melting of a late-lying or perennial snowbank yields a steady supply of water to the patchy wetland downslope. The extent of the wetland changes during the summer, expanding upslope as the snowbank shrinks. Vegetation is poorly developed on the upslope side of the wetland as it usually has a limited time of emergence from under the snow cover.

Groundwater-fed wetlands

Where groundwater discharges at the land surface, usually in a depression or at a slope concavity, a high water table is maintained locally in support of a patchy wetland. Although winter snow accumulation on the wetland is a good water source, groundwater in the active layer (the seasonally thawed layer on top of the permafrost) provides reliable water supply to sustain the wetland.

Valley bottom fens

A fen may occupy a flat-bottomed valley when wetness is maintained by surface and sub surface drainage from the

Wetlands of the Canadian Arctic, Figure 2 Conceptualization of occurrence of patchy wetlands in the Arctic.

adjacent slopes. It is a variant of groundwater-fed wetland without dependable water supply during the dry season, when the fen is hydrologically uncoupled from the hillslopes.

Wetlands due to lateral inundation

Lateral flooding of land on the banks of rivers, along the shores of lakes and at the coastal margins, gives rise to strips of patchy wetland. Riverine and lakeshore marshes are subject to large floods in the snowmelt period and become increasingly exposed as river and lake levels drop seasonally. Coastal marshes are saline in nature, and their extent and level of flooding are influenced by the tide. With isostatic rebound after deglaciation occurring in most of Canadian Arctic (areas subject to marine regression, shown in Figure 1), coastal marshes are gradually lifted above the high water mark, and over decades and centuries, the old marshes become dry land, while new marshes are created on the seaward side. Marine transgression (sea level rises relative to elevation of the land) also occurs in some other Arctic areas (Figure 1). There, new wetlands are created, altered, or drained in response to coastal submergence, tidal activity, and interactions with sea ice which can erode and modify the coastline.

Tundra ponds

Unique to the Arctic are tundra ponds that are formed inside low-centered polygons (patterned ground with raised rims of large cracks measuring 10^1 – 10^2 m in length enclosing polygonal-shaped central zone) or that occupy the enlarged cracks of ice-wedge polygons. Tundra ponds are usually found singly or in a cluster, the latter may or may not be connected by surface and subsurface flows (Woo and Guan, 2006).

Lake-fed and lake-bed wetlands

Outflow and seepage from lakes and large ponds may be sufficiently continuous during the thaw season to maintain patchy wetlands below the outlets. Water supply to the lake-fed wetlands depends on the lake level which generally declines after the snowmelt season. Lakes may have drained or dry out after a long period of low precipitation and high evaporation. Ponds and patchy wetlands may then be found on the former lake beds.

Extensive wetlands

Extensive wetlands situated in the Canadian Low Arctic and High Arctic can best be described as a mosaic of patchy wetland types: ponds, lakes, wet meadows, saturated ground, inter-mixed with patches of dry ground. There are wetlands where one or more components (e.g., ponds, wet meadows) can dominate the landscape (Woo and Young, 2006).

Wet terrain

Seasonal snowmelt is an important source of water for ponds, wet meadow, and wet ground. It recharges wetland

storage, enables strong hydrological linkages, and transfers sediment, terrestrial carbon, and nutrients. In the post-snowmelt season with warm, dry periods, evaporation losses and vertical seepage draw down the water table, lower the soil moisture content, and reduce the wetland storage. Hydrologic connectivity is generally severed between most ponds and wet meadows though linkages may endure locally where the wetland continues to be fed by late-lying snowbeds, creeks, and ground ice melt. Ponds and wet meadow zones dry out periodically due to rapid drainage which may be associated with thawing of their underlying coarse substrates or is caused by the presence of linear frost cracks lying at lower elevations that lead the water away from the wetlands (Abnizova and Young, 2010) (Figure 3). Timing and duration of summer rains are critical. Directly following snowmelt, they help to prolong high water levels and connectivity, but rainfall late in the season may not match evaporation losses and vertical seepage. However, if frequent enough, multiple small rain events may prime the wetlands for a high rainfall event (e.g., >20 mm) to rejuvenate floods and widespread runoff that match the spring freshets.

Ice-wedge polygon fields

Ice-wedge polygon fields are found in many parts of Arctic Canada. Polar Bear Pass, centrally located on Bathurst Island, provides an example of a network of low-centered polygons. It is an ecologically important area in the Arctic Archipelago and has been designated a wildlife sanctuary, offering a favorable habitat for migratory birds, caribou, muskox, and polar bears. Local Inuit frequently travel there to hunt for caribou. Many small tundra ponds occupy the shallow depressions surrounded by raised vegetated rims of the ice-wedge polygons. The ponds occasionally join with their adjacent sedge-dominated wet meadows to produce larger ponds or lakes (Figure 4). As of summer 2010, this low-gradient regional wetland (100 km²) included 4,800 regular (rectangular) and irregular-shaped ponds and two large lakes.

After a cold, long winter that lasts for about 9 months, snowmelt begins in early June. In 2–4 weeks, most of the snow on the wetland is depleted, ponds and wet meadows are recharged, and hydrologic linkages are established among all wetland types (ponds, wet meadows, and wet grounds). For ponds and meadows lying along the edges of Polar Bear Pass and adjacent to steep slopes and elevated plateaus, the influx of water and nutrients is prolonged for several weeks due to contributions from late-lying snowbeds on the lee of slopes and from the many ephemeral creeks draining from the uplands. This supplemental water supply buffers these wetland zones from water losses to high evaporation and to vertical seepage as the ground thaws in the summer. In the interior of the polygon wetland field, high ice content retards ground thaw to keep the water table elevated while some water is added to the wetland as the ground ice melts. There are minimal groundwater exchanges among the interior ponds, but evaporation causes a steady decline of the pond levels. Like other

Wetlands of the Canadian Arctic, Figure 3 Wet terrain in northern Somerset Island, showing different terrain types and their hydrologic linkages.

Wetlands of the Canadian Arctic, Figure 4 Ice-wedge polygon field in Polar Bear Pass, Bathurst Island, with *rectangular* and *irregularly shaped polygons*.

extensive wetlands, the status and the capacity of wetland storage (in the ponds and wet meadows) influence the wetland response to rainfall. Small and frequent summer rainfall events can raise the antecedent moisture storage

status. Freshet conditions (high pond levels, saturated wet meadows, and extensive runoff) can be raised by large rainfall events only if local storage capacities are exceeded (Young et al., 2010).

Deltas

Arctic deltas are often a combination of river channels, relatively high grounds such as levees, wetlands, and lakes (shallow ones are also considered as standing water wetlands). Deltaic wetlands are flooded by high flows associated with annual river breakups. The magnitude of floods is amplified by river ice jams that block the flow until the jams burst. However, spring freshet does not necessarily lead to complete inundation of all wetlands in a large delta. For example, shallow lakes of the Mackenzie River delta are grouped into categories of “no-closure lakes” that are flooded throughout the summer, “low-closure lakes” that are flooded each spring but infrequently flooded in the summer, and “high-closure lakes” that receive spring floods only during years with large freshets and are never flooded in the summer (Marsh and Hey, 1989).

Storm surges are due to wind stress on the water surface to produce a large displacement of water. Owing to low relief, episodic storm surges can produce backwater effects that raise the river stage to drown deltaic wetlands, as happened in the Mackenzie Delta on September 15–18, 1985 (Marsh and Schmidt, 1993). It produced backwater effect up the river to as far as over 200 km inland. The high water level led to flooding of many deltaic lakes and wetlands and affected the sediment, chemical, nutrient, and energy inputs to the deltaic area.

Flat lands

Most Arctic flat lands are associated with coastal plains. The high grounds are covered by tundra and dissected by ice-wedge polygons. Many lakes are present, including those that are partially or have completely drained. The tundra drops by low scarps of about 1–2 m to the floors of drained thaw lake basins, often occupied by marshy wetlands and water bodies. For areas undergoing isostatic rebound, the coastal plain has flights of subparallel raised beaches enclosing ponds, marshes, and fens.

With low relief but with little obstruction to snow drifting, winter snow is subject to redistribution to infill depressions and valleys. Spring is the major period of meltwater release. Substantial snowmelt runoff from upslope is the main water supply that replenishes wetland storage. Wetland areas expand to their maximum extent, while high flows are generated in the rivers crossing or issued from the wetlands. With good flow connectivity, runoff can reach the wetland quickly but can also be conveyed out of the wetlands efficiently. After snowmelt, the flooded areas contract quickly, terminating many of the temporary flow linkages within days. The isolated wet patches shrink in size during the summer as water is lost to evapotranspiration. Rain events may raise the water level but are much less effective in enlarging the wet areas than snowmelt. The above hydrologic behavior has been described by Bowling et al. (2003) for the wetlands of the Alaskan Arctic Coastal Plain which is contiguous with the coastal plains of Yukon and Northwest Territories.

Flow paths in wetlands

The flow within and out of wetlands follows surface and subsurface pathways. Wetlands undergo general inundation when ample water from vertical inputs (snow and ice melt, rainfall) and from lateral sources (lake and river floods, tidal rise, upland runoff) raises the water level on the wetland. The modes of surface runoff include (1) overland flow following ill-defined paths around low mounds or narrow strips of drier land on wetland surfaces, (2) spillage from puddles, ponds, and lakes as they become full, and (3) channeled flow in rills, gullies, and streams that cut through the wetland. Overland outflow and spillage take place when storage is filled to capacity and water spills over vegetated borders and pond rims. Channeled flow follows rills between tussocks and hummocks, cracks along and across the rims of ice-wedge polygons, and gullies enlarged through ground ice melt (Abnizova and Young, 2008). There may also be well-marked streams flowing across the wetland, with varying degree of hydrological exchanges between the river and the wetland depending on their relative water levels. These different modes of flow often alternate or merge with each other within a wetland.

Subsurface drainage of wetlands includes vertical seepage and lateral flow. Vertical drainage is limited by the presence of seasonal frost and permafrost not far below the surface, and is much affected by the hydraulic property of peat and mineral soil. As frozen soil rich in ground ice tends to be impervious, subsurface flow is largely confined to the thawed zone. Much water can seep into coarse soils and flow out of the wetland where the hydraulic gradient is steep (Abnizova and Young, 2010). Upon thawing, the peat and its living plant cover may be distinguished generally into a top layer that allows water to move more freely (called the acrotelm) than the more humified, compacted, and less porous peat of the bottom layer (known as the catotelm). When the water table resides in the acrotelm, much of the flow moves through its soil matrix as well as in the soil pipes formed in the peat. A combination of pipeflow and subsurface flow in the acrotelm constitutes quick flow, as distinguished from the slow flow in the catotelm and in the mineral soil below. Such a two-layer flow system (Carey and Woo, 2001) is common in organic soil terrain.

The delivery of water within and from an Arctic wetland depends on the connectivity of flow pathways. Spring freshet is the prime time for storage recharge, and once accomplished, surplus waters can be shed from the wetland. Although the overall snow cover pattern is similar between years, slight changes in snow distribution alter the runoff pathways and linkages within a wetland (pond to pond, pond to wet meadow, etc.). The prevalence of frozen grounds in all wetlands during snowmelt encourages flooding and overland flow, offering strong connectivity within the wetland and with nonwetland zones in the catchment, thereby allowing easy transfer of water and nutrients. After the melt season, water level drops, the

flooded and saturated areas contract, and flow linkages among the depressions and between flow conduits are weakened or broken. Nevertheless, connectivity may resume in the summer if heavy rainfall can raise the water levels above the storage capacity of the wet terrain. Such seasonal enlargement and contraction of wet areas are commonly observed in Arctic wetlands of Canada and Alaska. The fill-and-spill mechanism, applied to chains of lakes (Woo and Mielko, 2007), appropriately describes the expansion and contraction of surface ponding and flow connectivity. Ponds expand as they are filled. Spillage of individual ponds occurs when their levels reach the elevations of their outlet lips. Overflow provides runoff that establishes linkages among ponds and integrates the wetland drainage network.

The fill-and-spill principle also applies to subsurface flow as the ground thaws. Differential thaw rates within a wetland give rise to an uneven frost table with many troughs and depressions that temporarily withhold supra-permafrost groundwater from lateral drainage. When sufficient water is accumulated, subsurface flow occurs as water spills over the subterranean sill.

Hydrology of wetlands

Water balance

To survive over time, a wetland needs a positive water storage during most of the thawed season to maintain a high degree of saturation, necessitating the total water input to exceed cumulative water loss:

$$dS/dt = [P + Q_{in}] - [E + Q_{out}]. \quad (1)$$

Here, dS/dt is change in storage during time interval dt , $P = S_n + R$ is precipitation and includes both snowfall (S_n) and rainfall (R). Q_{in} is inputs into the wetland system from surface and subsurface sources. Losses of water from wetlands include evaporation (E) from open water and adjacent wet areas which tend to expand and shrink over a summer season, and water losses to groundwater and surface runoff from the wetland (Q_{out}). Table 1 presents values of water balance components for selected wetlands across the Arctic. At each site, only one to several years of study was carried out, and the water balance period usually spans over most of the thaw season, from snowmelt until late summer.

Wetlands derive their water from direct precipitation that includes rainfall and snowfall, the latter may be stored over winter and subsequently released as snowmelt, melting of ground ice which may have been held in storage seasonally or over longer periods, lateral inputs that can be spillage from lakes and rivers, coastal inundation, surface and groundwater inflows from nearby hillslopes, or from upstream catchments. There is much variability in rainfall across the Arctic. Table 2 summarizes the annual rainfall along a north-south transect of weather stations in central and western Canada where vast tracts of Arctic wetland are located. Rainfall decreases northward, from over 200 mm in the Low Arctic to 50 mm or less in

the High Arctic. On a mesoscale, wetlands in polar oases (many of which are in rain shadow areas) receive less rain than polar desert sites; greater exposure to open water and frequent passage of low pressure systems generally deposits more rainfall and high elevations have more precipitation (Young et al., 2006).

Snow is particularly important, and for Arctic wetlands, it is the total winter snow accumulation rather than snowfall of individual events that is of major hydrological consequence. Melting of snow replenishes storage deficits at the beginning of a new hydrological year so that wetlands start off with saturated conditions for plant growth and provides adequate storage to buffer against summer drought and evaporation losses. Despite months of accumulation, total snow accumulation is around 100 mm (snow water equivalent) in a given winter, reflecting the dry and cold environment. There are regional variations. For instance, snowpacks of <100 mm are the norm for polar oasis-type climate, while wetlands in the polar desert capture 100–200 mm and occasionally >200 mm in ponds situated in deep depressions (Abnizova and Young, 2010).

Between the termination of the main snowmelt season and the end of summer, much of the water in wetlands is lost to evaporation. Table 3 indicates that daily mean evaporation is usually lower in the High Arctic than in the Low Arctic, which has a longer thaw season without a snow and ice cover. However, during warm, dry summers in the High Arctic, daily rates and seasonal totals can approach levels typical of Low Arctic sites, even under polar desert climatic conditions (Young and Labine, 2010). Evaporation is lower at coastal wetlands (e.g., Prudhoe Bay in Alaska) owing to low air temperature, and foggy, damp conditions which reduce energy receipt. Further inland, advection from heated ground adjacent to the wetland accelerates evaporation (e.g., open water bodies in the Mackenzie Delta). In terms of wetland terrain units, ponds generally have higher rates of evaporation than wet meadow zones.

Limited records on seasonal outflow from wetlands are available to assess the ratio of runoff to precipitation, known as the runoff ratio or Q_{out}/P . Table 1 provides examples from wetlands in the Low Arctic and the High Arctic. The ratio seldom exceeds 0.50, suggesting that wetlands are effective in withholding water through surface storage (topographic depressions including ponds; water later lost to infiltration or evaporation), or releasing it directly to evaporation and lateral flow. At the end of the study years, wetland storage is often negative as the stored water is reduced by evaporation. Negative storage may also be an artifact of the duration of the study periods which often terminated around mid-August before the onset of late summer rainfall that can recharge wetland storage.

Seasonality

Other than coastal wetlands which are dominated by tidal rhythms, the delivery of water within and from an Arctic wetland is strongly seasonal. A freshet is common in the

Wetlands of the Canadian Arctic, Table 1 Components of water balance for selected extensive wetlands in Low Arctic and High Arctic Canada (all values in mm). Values from Alaska are provided for comparison

spring due to rapid melting of snow accumulated over the long Arctic winter. The amount, timing, and duration of snowmelt vary according to topography and its interaction with local wind in the High Arctic, with tall vegetation being an additional factor in the Low Arctic. Snowmelt season arrives later and is more protracted in the High Arctic

than the Low Arctic. Within the High Arctic, melt generally occurs earlier and ends sooner at wetlands in a polar oasis (e.g., Eastwind Lake, 80°08'N, 85°35'W) than in the polar desert (e.g., Creswell Bay, 72°42'N, 94°15'W). There are also large interannual variations. Figure 5 illustrates that, even for the same wetland, the timing and the duration of melt differ from year to year according to weather conditions. Cloudy, cool springs can prolong the melt season by a few weeks. Owing to the diverse terrain (ponds, lakes, wet meadows, dry and saturated ground) that constitutes the extensive wetlands, snow cover and melt patterns are also spatially and temporally variable, with deeper snowpacks persisting longer than thin snow patches (Figure 6). Melting of ice in the ponds and on wetland surfaces begins after the snow is ablated. Residual snow and ice often remains on the wetland at the time of spring flooding.

Wetland streams emerge from their winter dormancy of no flow or low flow when the snowmelt season arrives. The initiation of streamflow in wetland catchments lags behind snowmelt by 1–2 weeks, with a more extended delay for large rivers and in cold and cloudy springs. The delay is attributed to the time needed for the meltwater

^aindicates daily mean, otherwise the numbers indicate the range of daily evaporation during the study period

(1) to percolate the snowpack to reach the ground, including the refreezing meltwater to form ice lenses in the cold snow, or the possibility of infiltration into porous soils; (2) to satisfy wetland storage requirements, such as filling surface depressions and ponds; (3) to travel across the wetland as overland flow and through the thawed portion of the acrotelm; and (4) to clear the channels within the wetland which are usually infilled with snow and ice that block the flow. Spring peak discharges are attained when the wetland drainage network is connected for flow delivery, and peaks are magnified by snow and ice breakup events in the channels. For some large wetland rivers, peak discharge may not occur until over a week after the end of the main snowmelt season (Figure 7).

Subsequently, discharge recedes as evaporation intensifies and storage declines. Evaporation becomes active when wetlands are shed of their snow and ice cover, and the intensity of evaporation depends on the availability of water and energy, the surface to air vapor pressure gradient, and the intensity of turbulent motion. Surface cover (percentage open water and bare or vegetated land) and vegetation type (woody, vascular or nonvascular plants) further modify evaporation rates. When snow disappears from a wetland, the freshly exposed surface has a high moisture content. Ample available moisture and large

input of energy in June to early July enable high evaporation in the immediate post-melt period, as evidenced in the daily evaporation rates of a site near Creswell Bay in the High Arctic (Figure 7). Evaporation declines when the wetland becomes drier and solar radiation becomes lower in late summer. Superimposed on this seasonal trend are daily variations due to the weather: evaporation is much reduced on rainy days with low radiation input. Plant growth adds transpiration loss, but lichens and mosses, being nontranspiring, can hinder evaporation by cladding a dry cover over the wet substrate.

The frequency and duration of rainfall are important in the summer water budget, especially for ponds and wet meadows that do not receive reliable lateral water inflow. The amount of summer rainfall, as well as summer temperature, varies considerably from year to year, and extreme drought or wet events are experienced by Arctic wetlands (Young and Woo, 2003). Late summer rain can recharge ponds to snowmelt season levels, while streamflow may rise again in periods of intense or protracted summer rain. However, with a reduced storage status, the wetland becomes more effective in attenuating stormflow than it does with the spring freshet. Depending on antecedent moisture conditions and the amount of rainfall, Arctic wetlands may or may not show discharge

Wetlands of the Canadian Arctic, Figure 5 Between-year variations (2005, 2006) in the timing and duration of snowmelt due to differences in weather conditions at wetland sites in a polar oasis near Eastwind Lake, Ellesmere Island, and in polar desert at Creswell Bay, Somerset Island.

Wetlands of the Canadian Arctic, Figure 6 Uneven depletion of snow cover on the wetland and its surrounding dry lands during the melt season of 2010 at Polar Bear Pass. Residual snow and ice remains on the wetland at the time of the freshet, blocking or diverting the path of flow.

Wetlands of the Canadian Arctic, Figure 7 Outlet discharge (spring 2005) from wetland terrain near Creswell Bay, Somerset Island (see Figure 3), in relation to precipitation inputs and evaporation losses. The main snowmelt period is indicated (June 5–17, 2005).

response in the rainy period. By early winter, wetland streams stop flowing, or if a large river is fed by groundwater, baseflow continues under the river ice. The seasonal rhythm of streamflow, known as the wetland flow regime (Woo, 1988), is illustrated by the discharge of a small stream draining a low-gradient wetland complex near Creswell Bay (Figure 7).

Eventually, the wetland freezes as ground ice is formed in its saturated soil and pond water turns into ice. Sea ice formation lags behind river and lake ice, but coastal wetlands cease to be flooded when shore-fast ice is established. The snow that falls after wetland freeze-up is subject to redistribution by winds, often filling all

depressions and obliterating topographic irregularities on the wetland surface.

Wetland evolution and impacts of change

The natural evolution of Arctic wetlands follows some regular trajectories. Zoltai (1988) generalized the evolution in several stages. Deglaciation leaves a landscape with low ridges and troughs, pitted with depressions that are isolated or linked by drainage channels. In some areas, previously glaciated or otherwise, the draining of lakes through breaching of their rims or through thermokarst process also creates shallow depressions. Wetlands are formed in the depressions with gradual peat accumulation.

Peat growth tends to be slow because the cold environment does not favor vegetation development. Over time, paludification (the process of peat expansion to cover previously dry land) leads to an extension of the peat cover beyond the confines of the original depressions. Continued peat growth can raise the wetland above the regional water table, and a perched water table is formed within the peat. For Arctic wetlands, another process is also common, i.e., the growth of ground ice that heaves the peat into mounds and plateaus. These raised features retain or shed water to their surrounding wetlands.

In Arctic regions, there are close relationships among the evolution of peat and wetlands and development of permafrost. Woo and Young (2003) postulated that reliable local water supply in a semi-arid Arctic environment sustains a high water table that supports the growth of hydrophytic vegetation. Peaty materials accumulate when plants die and the peat provides insulation to the underlying ground ice against summer melt. Eventually, increase of ground ice in the soil leads to permafrost aggradation together with thinning of the active layer. Then, the shallow thawed zone would need only a small amount of water for its saturation, and this facilitates the maintenance of the wetland. These feedback mechanisms are self-perpetuating unless interrupted by natural or human disturbances.

Sea level change can alter the supply of water to coastal zones when gradual uplifting of the land deprives the coastal wetlands of frequent floods or can enhance flooding when coastal areas are subject to submergence. Geomorphic processes such as mechanical and thermal erosion, and shifting of shoreline and river channels, may alter the drainage pattern so that an existing wetland is lost to erosion or is left dry. Wild fire is a large hazard in the forested subarctic but is less so in the Arctic, though tundra fires have been observed. Climate warming, however, can affect wetlands on a regional scale. With early melt and perhaps a reduction in snowmelt water supply and increased evapotranspiration, wetlands become more prone to summer droughts and the peat risks accelerated decay. Wet meadow vegetation may convert to woody species, eventually altering grazing patterns of arctic ungulates (Hill and Henry, 2007) and loss of breeding habitats for wildlife, especially migratory birds.

As resource development and human settlements push northward, anthropogenic activities have impacts that may outpace natural changes. Mining activities can strip away protective wetland peat covers, exposing pockets of ice-rich permafrost to rapid thaw, leading to ground subsidence as well as the release of carbon and nutrients locked in the soil. Depending on the size and extent of the disturbance and characteristics of the underlying materials (soil texture, ice content), thermokarst or melt subsidence may produce new depressions prone to wetland formation. One leading concern for the Low Arctic is the risk of oil spills from both onshore and offshore exploration and production. This problem may be exacerbated by leakages from corroded pipelines due to

permafrost thaw and by incidence of oil spills in riverine and estuarine wetlands. Mining, oil and gas exploration and development also require a great deal of freshwater to support ice road and ice pad construction, for drilling mud, and domestic water supply. Depletion and contamination of water in the ponds, lakes, and streams by industrial uses can affect wetland water balance and quality and permafrost thermal regime, to the detriment of wildlife habitats.

WETLANDS: CLASSIFICATION, DISTRIBUTION, FUNCTION

Lars Lundin

Department of Aquatic Sciences and Assessment,
Swedish Agricultural University, Uppsala, Sweden

Introduction

Wetlands constitute a large variety in types and several classifications exist. Basic is hydrological conditions such as those providing hydrophilic vegetation to prevail. Water-saturated conditions often exist with direct connections between groundwater aquifers and wetland waters, i.e., open aquifers. In wetlands, saturated water conditions prevail near the surface with a water level close under the soil surface or often being at that level or even higher making up shallow surface water bodies.

Wetland functions in the landscape relate to environmental services and enhancing biodiversity conditions. Ecological functions besides those related to high biodiversity addresses water resources as contributing in the water balances and also water quality. However, wetlands often support high water content and turnover but also in drought conditions might store water being unfavorable to surrounding water bodies and downstream water courses. Regarding water quality, wetlands act as accumulation and sedimentation areas storing many chemical elements, especially base cations and metals but furnishing organic compounds and protons, meaning relatively high hydrogen and carbon release in relation to surrounding land. This would provide fairly high water color, with, in relation to surrounding land, often low pH.

Further, important functions of wetlands are storage of organic matter and thereby carbon; with the presence of sinks for carbon dioxide but in relation to greenhouse gases, there might instead be natural release of methane

or/and nitrous oxide turning the wetland into a source for gases when related to warming potential. The emissions of gases are though dependent on nutrient status and with higher nutrient level, the natural release of gases will be higher, also considering carbon dioxide being stored more comprehensively in poor sites.

Wetland types

The wetlands actually cover a wide range of water-related habitats, and internationally, probably the Ramsar convention 1971 would be the most well-known classification (Matthews, 1993). Wetlands here cover areas from the oceanic types where coastal areas with water depth up to 6 m at low tide are included. Vast areas would be considered in this context. In the Nordic region and also in North America, changes in land level due to isostatic and eustatic processes influence formation, especially related to coastal wetlands. Land-lift furnishes building up conditions while subsidence would have deteriorating impacts. Further wetlands are shallow inland waters, being limnic wetlands related to freshwater, and water courses, swamps, and marshes (Rydin and Jeglum, 2006). Turning closer upland to terrestrial types there are wet meadows, inundation areas, mires, and peatlands.

Wetlands include as mentioned above many types of moist and wet habitats. Those mainly being made up of actual water bodies would be sorted as wetlands while the types where organic matter has accumulated form mires and peatlands, and open water only exists on small parts of the whole peatland.

Geographical distribution of wetlands

Wetlands, covering 6% of the world's land area (Maltby, 1986), are of course abundant to water bodies and therefore coastal areas around the globe furnish the main part of wetlands, and these areas are often fairly highly populated and it is considered that two third of the world's population are living in connection to and being dependent on wetlands. Probably, these are of the types being more or less open water bodies while the number of people in peatland areas is fewer.

The geographical location of peatlands shows a distribution dominated by high latitudes on the Northern hemisphere where in the temperate and cold belt 90% of the peatlands of the world exist. However, peatlands are found more or less around the whole globe but preferably in areas related to high humidity while arid areas mainly lack peatlands. In parts of the world outside the high latitudes of the northern hemisphere, other types of peatlands may form, and in tropical regions, there are tropical peatlands, being, to a large extent, formed from wood debris and other macroorganic substances. These areas are often found in connection to larger water bodies such as the sea, big lakes, or rivers.

The areal coverage of peatlands extends over 3% of the land area of the world, and countries with territories in the boreal zone dominate the hosting of peatlands. Large areas such as Canada and Russia host 43% and 25%,

respectively. In third place, there is a part of USA, i.e., Alaska with 13%. However, already in the fourth place a country outside the northern part shows a peatland area of 7%, i.e., Indonesia with tropical peatlands. Other, bit smaller countries follow with Sweden making up 3% of the world's peatlands, i.e., c. 10 Mha, while Finland, Suomi, meaning mire land, with c. 9 Mha with a coverage of 2% anyhow includes the largest proportion of peatland of the country area with about 33%. A neighboring country, Estonia, with a territory of only c. 45,000 km² has a peatland share of 22% making up about 1% of the world's peatlands (Lappalainen, 1996).

Peatland development

Peatlands are often also referred to as mires but could not be considered synonymous as mires are defined as areas with hydrophilic vegetation and ongoing organic matter accumulation. Often there is also a restriction on organic matter thickness as referred to peatlands where 0.3 m is often considered required thickness to qualify as peatland. Mires are not limited by thickness and actually peat could be formed in more shallow layers than 0.3 m. Peatlands, on the other hand, have stored peat for some time but might be under land-use, such as forestry or agriculture, often requiring drainage and turning the natural organic matter accumulation into decomposition without ongoing peat accumulation.

In formation of peatlands, three main types of processes are considered, and it is interesting that both decreasing and increasing wetness may form peatlands. The most direct formation type is what is called primer peat formation, directly from a shoreline when water is retreating and could be found in sea shorelines. Secondly, the sedimentation and overgrowing of open water bodies is a rather common formation referred to as terrestrialization. However, the third formation is somewhat opposite where the mineral soil surface often in small depressions are more or less sealed by fine material providing water storage where peat-forming vegetation may colonize and organic matter accumulate. Such processes are called paludification, which actually make the landscape more wet. This type is most common and forms organic matter coverage of the landscape providing possibilities to expand and increase the peatland coverage. It should be kept in mind that peat formation in large parts of the northern hemisphere has been an ongoing process since the last ice age and peatlands that formed during that period still exist there now. This process has so far not stopped.

Peatlands are built by organic material first being deposited in shallow water bodies such as lakes and seashores. With time, new plants grow and decay, store organic matter continuously, and would be decomposed only a little because of lack of oxygen. Such conditions relate to water saturation and stagnation which is crucial for low decomposition and net accumulation of organic matter. In later stages, where storage has been ongoing, open water bodies will be overgrown and eventually such

surface water and groundwater fed habitats get colonized by plants with high water storage capacities. Such types are dominated by *Sphagnum* mosses storing precipitation efficiently, providing possibilities to grow higher and higher, leaving the contact with the mineral soil groundwater and mainly being fed by poor precipitation water. Then a bog is formed with the typical poor vegetation dominated just as mentioned by *Sphagnum* mosses and with only precipitation water input. Often such bogs are surrounded by a lagg area, actually being a groundwater-fed system where there is discharge from both mineral soil groundwater from surrounding uplands and bog water from the higher lying bog formation. Together, such combinations of bog and lagg fen form mire complexes of bog type.

Mainly wetlands are formed in locally low-lying land, often formed as depressions and the origin comes from high groundwater levels. In later stages, as described above, the accumulation of organic matter could turn the types into raised bogs being supplied by solely precipitation. In some cases though, with high precipitation often in mountain areas, peat may be formed mainly because of the excess humidity, and peatland could spread and cover the landscape following the contours and forming blanket bogs common in areas with maritime connections such as Ireland, Scotland, and Norway.

Mainly, however, peatlands depend on groundwater conditions and types depend on the origin of the water. Inflow of water provides prerequisites for the types developed and characteristic properties would prevail as described by Dembeck and Oswit (1996). Besides the fluvatile wetlands described below there are:

- Soligenous mires receiving discharging groundwater entering the area from upland mineral soils
- Water head peatlands with groundwater under piezometric pressure
- Oozing water peatlands with a more diffuse groundwater flow
- Topogeneous peatlands with water entering as groundwater or overland flow to local, partly isolated landscape depressions
- Bogs being fed by precipitation

Peatlands of fen type are formed in connections to inundations. Rivers may form other inland wetlands especially in low-lying areas being temporarily inundated at high flows, such as at spring snowmelt when the water level may rise several meters. These kinds of wetlands would be called fluvatile wetlands often extending over large areas of river shorelines. In connection to lakes these would also temporarily have high water levels, and low-lying surrounding land is inundated with wetland characteristics and peat formation.

Hydrological functions of peatlands

Peatlands are often divided into two main groups, i.e., fens and bogs. Related to water bodies, in bogs pools would be found but constitute relatively small areas and are surrounded by fairly large organic matter areas. As

mentioned above, water input to peatlands could be from different sources. Fairly high precipitation, at least in relation to evapotranspiration, would be a prerequisite. Direct precipitation to the land surface adds water to the system and bogs are totally dependent on this atmospheric inflow. However, groundwater in deeper layers provides a hydrological situation where the bog water would be kept in the formation for long time. The water flow in such areas most often are from the surface down into the lower layers of the soil forming what is hydrologically called inflow or recharge areas. In fens, water is of course also added from precipitation, but more importantly there is a direct inflow from surrounding groundwater meaning surface water formation in discharge areas. Outflow from such fens, then would be a mixture between rain water and groundwater.

Hydrochemically the bog water would be fairly poor in nutrients, and with a soil formed by *Sphagnum* plants, the pH would be low. Actually, bogs are acid with pH values around 4. Fen water, however, depends on the type of feeding groundwater and the mineral upland soils. There could be mainly silica sands and then the fen vegetation would be similar to bog vegetation and water nutrient poor. Often though, medium rich bedrock has formed a mineral soil keeping the water quality on medium nutrient richness with pH values between 5 and 6. Higher values may prevail in areas with calcareous bedrock or soils where pH could be up to 8 with a rich flora.

Water turnover in peatlands mainly are slow because of low hydraulic gradients and conductivity. Only in surface layers, the acrothelm (Rydin and Jeglum, 2006), higher conductivities occur providing high outflows in situation with excess water. In fens, such high water levels might prevail for longer periods due to inflowing groundwater from the uplands. In bogs, the high water flows are short-lived and directly dependent on input by precipitation. A short time after ceasing input, water levels are lowered into the somewhat deeper layers in a 0.2–0.5 m depth, the catohelm (Rydin and Jeglum, 2006), where hydraulic conductivity is low providing small or almost no water flow. This means, in wet situations peatlands provide high flows but in drought the water is mainly stored in the peat and the contribution to surface waters is withdrawn. The considerable contrast in water flows are more pronounced in peatlands as compared to mineral soils having better possibilities to maintain at least low water flows and a little water to water courses.

However, as a wetland element in the landscape, peatlands contribute to the biodiversity by being mainly a wet body in a drier landscape and thereby furnishing special and valuable hydrological conditions.

WIND WAVES

Luigi Cavaleri

Institute of Marine Sciences, Venice, Italy

Synonyms

Water waves; Waves; Wind sea

What is a wind wave

Oscillations of a (water) surface can be generated by a large variety of reasons. In this chapter we will describe the ones due to the action of wind on the surface, their generation, evolution and effects.

The basic idea of a wave is a regular sinusoidal oscillation of the surface, this oscillation being characterized by height H , period T (hence frequency f and length L) and direction. In deep water, i.e. on a depth larger than half the wavelength, period, frequency and length are related by

$$f = 1/T \quad L = (g/2\pi)T^2 \quad c = L/T = (g/2\pi)T \quad (1)$$

with g the gravity acceleration and c the phase speed or celerity.

It is everybody experience that the appearance of a water surface under the action of wind is not regular. Rather, at a first glance it looks very confusing and chaotic. A more attentive look reveals some regularity in it, with dominant period and direction, and a characteristic (significant) wave height. These three quantities are connected to, and derived from, the full information available from the wave spectrum. The wave spectrum summarizes the surface conditions present at a given position or in a certain area. In general these conditions change in space and time, and so does consequently the spectrum.

Wave generation and development

When wind starts blowing on a water surface, at first very small ripples are generated. Soon these initially little waves grow both as height and length (hence period), and keep increasing till when the wind blows and is strong enough to sustain their growth.

Three processes concur to this development. The first one is the actual transfer of energy and momentum from wind to waves (Miles, 1957; Janssen, 2004). The higher the wave, the more effective is the transfer, so that the growth tends to be an exponential very effective process.

The presence of energy at different wave components and, under certain resonance conditions, the exchange of energy among the components, lead to a progressive shift of energy toward longer wavelengths (hence longer periods and lower frequencies). Because there is an obvious limit to the ratio height/length (hence steepness) of a given wave, this transfer allows larger wave heights to be present. This corresponds to the familiar increase of the wave heights while propagating under the action of wind.

A third process helps in keeping the system in balance. Wave breaking (white capping under the action of wind) naturally dissipates the excess of energy when single waves on the surface grow beyond their physical limit. For an ideal wave the theoretical limit is close to $H/L = 1/7$. In practice, due to the interaction among the various wave components, in a wind sea the limit is much lower, $H_s/L = 0.04$, with H_s the significant wave height and L the dominant wavelength.

As a matter of fact, most (more than 90%) of the energy put by wind into waves is rapidly dissipated by white capping. The actual growth of a wind sea is due to the positive difference between input by wind and wave breaking, with the energy transfer moving the peak period, hence wavelength, toward higher values.

The intensive breaking, or white capping, corresponds to the single, but highly frequent and distributed, white foamy crests that we see on a surface under the intensive action of wind.

On an infinite surface wind waves would grow till when the dominant waves move with a phase speed lower than the wind speed. Waves moving faster do not receive any direct input by wind. The time and space required to reach such conditions (fully developed sea, see Pierson and Moskowitz, 1964; Alves et al., 2003; Babanin, 2011) increase rapidly with the wind speed, reaching orders of many hours or days and hundreds or thousands of kilometers. In most of the cases, and more so in lakes and reservoirs, this condition is far from being achieved, and the wave conditions are limited either by the time the wind has been blowing (time limited) or by the amount of space available (fetch limited).

Waves propagate on the water surface. In deep water the crests move with c velocity (see Equation 1). However, energy, i.e., the wave system as a whole, moves with the group velocity that is only half this speed, i.e.,

$$c_g = c/2 = L/(2T) = (g/4\pi)T \quad (2)$$

Starting with the wave spectrum at given time and position, this implies that the different wave components of the spectrum propagate at different speeds. As a consequence, an observer far from the area of

generation will be reached first by the longer period (hence longer wavelength) waves, and progressively in time by the shorter and shorter ones. These waves have a more regular, often almost sinusoidal, appearance, and they are referred to as swell.

Waves in lakes and reservoirs

Given that, for a certain wind speed, the development of waves depends on fetch and time, it is intuitive that waves in a limited amount of space cannot reach the high conditions achievable on the large expanse of the oceans. Everything depends on the dimensions of the basin we are considering. Large basins as the Great Lakes of North America have dimensions comparable to that of some inner seas, and wave conditions can be comparably severe. However, also in relatively small lakes conditions can sometime be hazardous. The local hazard does not depend only on wave height, but also on the number of breaking waves. For a sustained wind speed, e.g. 15 m/s or more, this number is largest at the very early stage of generation. Therefore in a small lake under a strong wind possibly every single wave is breaking. Notwithstanding the limited wave height because of the short fetch, the surface will then appear as a continuous series of breaking waves that will make the navigation of small boats rather difficult.

Numerical methods for the evaluation of the wave conditions will be soon discussed. However, a simpler approach suffices for most of the small lakes to have an idea of the possible wave heights. In basins with limited dimensions we can assume with good approximation that the wind is uniform in space and time. In this case some simple relationships hold between the wind speed U , fetch x , and the dominant wave height H_s and period T (or frequency $f = 1/T$).

$$H_s = 2.88 \times 10^{-3} g^{-0.55} U^{1.1} x^{0.45} \quad (3)$$

$$T = 0.459 \times g^{-0.73} U^{0.46} x^{0.25} \quad (4)$$

Derived from Equation 3, Figure 1 provides the maximum significant wave height as a function of wind speed U (m/s) and fetch x (km). In the figure the fetch (one line for each x) varies with an approximately geometric progression from 0.1 to 100 km. It is clear that, provided we are dealing with a large and prolonged storm, as it can indeed be the case, large basins can experience very severe storms.

While the significant wave height H_s summarizes in a single figure the wave conditions at given time and position, smaller and larger single wave heights do exist. Their possible values are well represented by the Rayleigh distribution

$$p(h) = \frac{H}{4 \frac{H_s^2}{16}} \exp \left(-2 \left(\frac{H}{H_s} \right)^2 \right) \quad (5)$$

where $p(H)$ represents the probability of encountering a H high wave in a sea characterized by significant wave

Wind Waves, Figure 1 Maximum significant wave height (meter) as a function of wind speed (m/s) and fetch. Fetch (see legend) is expressed in kilometers. The fetch values, in an approximately geometric progression, increase from the lower to the upper line.

Wind Waves, Figure 2 Distribution of the probability of encountering single waves of height H in a sea characterised by 1 m significant wave height.

height H_s . As an example [Figure 2](#) shows the Rayleigh distribution for $H_s = 1$ m. It is worth noting that within the time of a few thousands waves, i.e., well within the duration of a storm, single wave heights as high as twice H_s are to be expected.

Kinematics, bottom and coastal effects

The presence of waves implies the motion of the objects on the water surface. For a sinusoidal wave the motion of a floating object is a circle with diameter equal to the wave height repeated with uniform velocity u every T seconds. It follows

$$u = \pi H / T$$

Surface motion implies also the motion of the underlying water layers. However, this motion attenuates rapidly with depth according to

$$d = H e^{-kz} \quad u = (\pi H / T) e^{-kz}$$

d being the extent of the motion and u the associated velocity. z is the depth we consider and k is the so called wave number $k = 2\pi/L$.

In practice at a depth equal to half the wavelength the motion is reduced to 4% of its surface value. At a depth equal to the wavelength there is hardly any motion left.

When waves move in shallow water, in practice when the depth h is smaller than $L/2$, waves feel the bottom. Their kinematics changes according to

$$c = (gT/2\pi)\tanh(2\pi h/L) \quad L = (gT^2/2\pi)\tanh(2\pi h/L) \\ c_g = 0.5c(1 + 2kh/\sinh(2kh))$$

In very shallow water these expressions simplify to

$$c = c_g = \sqrt{gh} \quad L = \sqrt{gh}T$$

The interaction of waves with the bottom has a double effect. On one hand it implies the dissipation of part of the wave energy, hence a reduction of their height. On the other hand, typically for sand or mud bottom material, it may lead to abundant suspended matter, hence to a change of the water characteristics, e.g., transparency or reflectivity.

Due to the dependence of wave celerity on depth, waves in deeper water move faster. In coastal and shallow areas this may imply the deformation of the long crests with possible focusing of the wave energy on certain zones. Refraction, as this process is called in relation to the similar process in optics, may lead to substantially larger, or smaller, waves in certain areas. Holthuijsen (2007) provides a good description of the process and suitable examples.

Measurements

A very large variety of instruments exists to measure water waves, the most convenient one depending on the wave conditions (typically wave heights) and situation we are dealing with. Moving from the low to the large wave heights, the possible instruments include capacitance wave gauges, laser beam, external or submerged acoustics, currentmetres measuring the orbital motion, submerged pressure transducers, and recording the motion of a surface following buoy. Some of these instruments require a fix support, either a pier or an offshore structure. Some others, as pressure transducers or currentmetres, when placed on the bottom and to be able to detect a signal, can be used only in shallow water. Buoys need to be moored on the bottom, but this is usually done till several hundreds meter depth. For large basins significant wave heights can be measured by satellite altimeters. Given the size of the ground area explored by each single measurement (a few kilometer diameter) and the spatial interval between adjacent orbits, this is only possible on large lakes.

Wave induced currents and turbulence

Currents in lakes may be due to the inflow of water at one end and possibly the outflow at another location. However, wind does have its profound effect on lakes.

Wind blowing over a water surface acts, via the intermediate generation and breaking of water waves, on the underlying layers. In a relatively short time, this leads to a current that attenuates with depth. The actual depth reached by the current increases with wind speed and time.

The effect can be much more intense close to the coast. Here incoming waves break, either because of shallow water or because they impact on the coast. If, as it is often the case, the wave direction is not perpendicular to the coast, their longitudinal component leads, via the coastal breaking, to a current adjacent and parallel to the coast. Combined with the associated suspended matter, this may lead to a substantial transport of coastal material, and consequent erosion and accumulation.

Via their surface breaking and their orbital motion below the surface, waves have a profound effect on the characteristics of the upper layers. In the lakes there is often, especially in the warmer periods of the year, a relatively warm upper layer on top of the deep cold one. The depth of the thermocline, the surface of discontinuity between the two layers, may vary from a few meters to several tens of meters in the larger and deeper basins. The underwater turbulence associated to waves may lead to a mixing of the two layers, to a consequent smoothing of the discontinuity and to an increase of the depth where we find the lower cold water.

Wave forecast

For a given geometry of the basin, water wave characteristics depend strictly on the wind conditions throughout the basin. The physics of generation, dissipation, evolution and transport of wave energy is a consolidated matter (see Komen et al., 1994; Janssen, 2004; Janssen, 2008; Babanin, 2011). Associated to the high quality meteorological forecasts presently available (see ECMWF for a full panorama of the latest statistics), this has allowed the development of sophisticated numerical systems for the forecast of water waves. Typically this is done at the global scale, which implies that only very large lakes can be considered, e.g., the Great Lakes of North America (see, e.g., Lalbeharry et al., 2009). Smaller lakes can be considered by numerical models running on limited areas, hence in general with higher resolution. Such an approach makes sense when the lake is large, and wind and wave conditions change appreciably from place to place. For smaller water surfaces a more pragmatic approach based on formulas Equations 3 and 4, or Figure 1, is frequently the most practical solution.

Summary

Wind generated water waves may reach substantial heights also in lakes. The height of waves increases increasing wind speed, fetch and time. Given two of these variables, the value of the third one will put a limit to the achievable heights.

Wave conditions at given time and position can be summarized into the local significant wave height H_s , mean period T_m and direction θ_m . For a given H_s different single wave heights can be expected, up to typically twice the significant wave height during the duration of a storm.

Waves lead to a number of effects on a lake: currents, suspended matter and its transport in shallow water (and)

close to the coast, a substantial mixing of the upper layers and possible reduction of the transparency.

Waves can be measured with a variety of instruments. The choice depends on the range of the expected wave heights, on the location (deep or shallow water, close to the coast or to a structure or offshore), and on the dimensions of the basin.

Sophisticated numerical systems are regularly used for wave forecast. For a given basin the necessary information is the evolution in time of the wind fields over the basin. While this is regularly done on the Great Lakes of North America, smaller lakes are considered in higher resolution models used on specific areas of interest. For smaller basins a direct evaluation, via the wind speed, based on general formulas relating wind speed U and fetch x may be a convenient solution.

WORLD LAKE DATABASE: INTERNATIONAL LAKE ENVIRONMENT COMMITTEE FOUNDATION (ILEC)

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

The International Lake Environment Committee Foundation (ILEC) (www.ilec.or.jp) was established in 1986. Since then ILEC has collected, in a systematic

manner, environmental and socioeconomic data of important (significant for human beings) lakes and reservoirs worldwide. Accordingly, the World Lake Database was constructed.

The World Lake Database

Currently the World Lake Database holds more than 500 lakes from 73 countries. The database was established in cooperation with UNEP.

The main data categories are:

1. Location
2. Description
3. Physical dimensions
4. Physiographic features
5. Lake water quality
6. Biological features
7. Socioeconomic conditions
8. Lake utilization
9. Deterioration of lake environment and hazards
10. Wastewater treatment
11. Lake improvement works
12. Development plans
13. Legislative and institutional measures for upgrading lake environment
14. Sources of data

A report of each lake providing the above categories can be obtained through a link in the database.

A search for a lake may be made by name, by country, by free word from: www.ilec.or.jp

The areas covered are:

- Africa
- Asia
- Europe
- North America
- Oceania
- South America

A typical lake report from the database gives:

- Lake name
- State
- Country
- Latitude
- Longitude
- Altitude (m)
- Surface area (m²)
- Volume (m³)
- Maximum depth (m)
- Mean depth (m)
- Water level control
- Normal range of water level (m)
- Length of shoreline (m)
- Residence time (year)
- Catchment area (m²)
- Hours of bright sunshine (h)
- Freezing period
- Mixing type

- Annual fish catch (t/year)
- Total N loading (t/year)
- Total P loading (t/year)
- Population
- Population density
- Water usage
- Land use

WORLD LAKE VISION

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Concept of the World Lake Vision

The concept and necessity for the World Lake Vision (WLV) was developed by the Scientific Committee of the International Lake Environment Committee Foundation (ILEC, website: www.ilec.or.jp) at the second World Water Forum, which was held in The Hague, the Netherlands, in 2000.

The WLV was subsequently developed during 2000–2003 as a cooperative effort initiated by the ILEC, and was unveiled at the third World Water Forum, held in Shiga, Japan in March 2003.

Prepared during 2006–2007, the World Lake Vision Action Report (WLVAR) was published in 2007, as to follow-up to the implementation of the World Lake Vision.

The WLV has been accepted around the world as the guidebook for lake management, with the original English version having already been translated into eight different languages.

The earth's freshwater

The WLV points out that only about 2% of the earth's water is freshwater, and even most of it being locked up in the form of icebergs and glaciers, or else located deep underground beyond easy human reach. Nevertheless, even this relatively small proportion of the world's freshwater would be sufficient to satisfy the world's population if it were evenly distributed and protected from degradation, neither of which is the case.

The WLV indicated that lakes play a fundamental role in the global water cycle, and that more than 90% of all the liquid freshwater on the earth's surface at any given instant is contained in natural and artificial lakes.

Managing international lake systems

The WLV Report confirms that many lakes in the world are shared by two or more countries, a situation that can sometimes be a problem. The unsustainable use of water from a shared lake by one or more countries can result in international tensions.

Threats arising within drainage basins

Withdrawing or diverting excessive quantities of freshwater can reduce the water levels and volumes in lakes to the extent that their water quality and the biological communities they support can be seriously threatened. A dramatic example highlighted in the WLV Report is the demise of the Aral Sea as the result of the significant diversion of the lake's inflow tributaries for agricultural irrigation during the last 50 years. Another example is the water withdrawals by Israel, Jordan, and Palestine from the Dead Sea, the world's saltiest lake, is 417 m below sea level. Excessive water withdrawals from the Jordan River from both its north and south reaches has reduced the river's flow by 25%.

Excessive nutrient loads

The WLV Report notes that phosphorous and nitrogen are the primary nutrients that can cause cultural eutrophication, the accelerated growth of aquatic plants to nuisance levels, with accompanying degradation of water quality and interference with human water uses. Blue-green algae species are detrimental to both stock and human health, and can cause the production of trihalomethane precursors.

ILEC also developed "World Lake Database," in cooperation with UNEP, which includes data for more than 500 lakes from 73 countries.

The main data categories in the "World Lake Database" include:

1. Location
2. Basin description
3. Physical dimensions
4. Physiographic features
5. Lake water quality
6. Biological features
7. Socio-economic conditions
8. Lake water utilization
9. Deterioration of lake environment and hazards
10. Wastewater treatment
11. Improvement works in the lake
12. Development plans
13. Legislative and institutional measures for upgrading lake environment
14. Sources of data

A major contribution of the WLV is the development of seven guiding principles for managing lakes and reservoirs, as follows:

Principle 1: A harmonious relation between humans and nature is essential for the sustainable use of lakes.

Principle 2: A lake drainage basin is the logical starting point for planning and management actions for sustainable lake use.

Principle 3: A long-term, preventative approach directed at preventing the causes of lake degradation is essential.

Principle 4: Policy development and decision making for lake management should be based on sound science and the best available information.

Principle 5: The management of lakes for their sustainable use requires the resolution of conflicts among competing users of lake resources, taking into account the needs of present and future generations and of nature.

Principle 6: Citizens and other stakeholders should be encouraged to participate meaningfully in identifying and resolving critical lake problems.

Principle 7: Good governance, based on fairness, transparency, and empowerment of all stakeholders, is essential for sustainable lake use.

The seven principles identified above were used in analyzing the experience and lessons learned from a number of case studies by the WLV Committee, which was the basis for the subsequently developed WLVAR. The WLVAR focused on 27 lakes located in six continents. Six of the case study lakes were the largest in the countries in which they were located (Lake Chapala in Mexico, Laguna de Bay in the Philippines, Lake Poyang in China, Lake Biwa in Japan, Lake Taupo in New Zealand, and Lake Balaton in Hungary). The other case study lakes participating in the WLVAR were:

Asia

- Sentarum (Indonesia)
- Daecheong (Korea)
- Seven Crater Lakes (Philippines)

South Asia/India

- Bhoj Wetlands (India)
- Chilika (India)
- Hussainsagar (India)
- Powai (India)
- Lonar (India)
- Ujjani Reservoir (India)

Africa

- Victoria (Kenya, Tanzania, Uganda)
- Nakuru (Kenya)
- George (Uganda)
- Kariba (Zimbabwe)

Europe

- Constance (Austria, Germany, Switzerland)
- Baikal (Russia)
- Barton Broad (UK)

Latin America/Caribbean

- San Roque (Argentina)
- Fuguene (Columbia)
- Chapala (Mexico)

North America

- Champlain (Canada, USA)
- Kelly (USA)
- Waterford Impoundment (USA)

The Lake Baikal delta and a Slovakian impoundment also were included in the study (see Table 1 and Figure 1, both of which were reproduced with the kind permission of the WLV).

In reviewing the results of the case studies in the WLVAR, it was clear that not all the WLV Principles could be applied with equal ease, as shown in Table 1.

Since many of the lakes in the WLVAR survey have been studied prior to the development of the seven principles, the primary task facing the authors of the case study reports was to determine the extent to which the seven Principles could be used to guide lake basin management.

World Lake Vision, Figure 1 Location of the 27 lakes of the case study in six continents.

The study results indicated that some of the Principles were easy to implement in most cases, while others were more difficult to implement. A general observation based to the WLV Report was that Principle 4 appeared to be the easiest Principle to implement for most of the case study lakes, while the most difficult to implement were Principles 5 and 7.

Implementing the WLV

There may be some eight million lakes in the world today. Many are well known to us, while others may still not have been named. Further, some may be so remote that accessibility to them is difficult, while others may only have been seen from space. It is the purpose of the proponents of WLV, therefore, to disseminate information from as many countries as possible on the world's lakes.

"The world's lakes, which are a primary source and storehouse of the world's easily accessible freshwater, will be a critical arena in the great transition to a society which sustains itself without degrading and depleting its own natural foundation. Many of these lakes are already in jeopardy" (WLV, 2003).

The aim of the WLV is to highlight this growing concern with the world's lakes and reservoirs, and to identify the need to manage these important waterbodies for their sustainable use, including undertaking activities and programs to ensure their long term health.

XIAOLANGDI RESERVOIR'S ROLE IN WATER AND SEDIMENT REGULATION

Zhu Xiaoyuan, Pang Hui
Bureau of Hydrology 2, Ministry of Water Resources,
Beijing, People's Republic of China

Introduction

Xiaolangdi reservoir plays a significant role in flood control of the lower Yellow River and sediment reduction since it was built. With its construction, the flood prevention and sedimentation situation in the lower Yellow River has greatly improved. In addition it increases the available water for people along the Yellow River and related areas. Three water and sediment regulation experiments have been carried out using Xiaolangdi reservoir and other reservoirs to further realize the rules on water and sediment movement and make full use of flood water to scour the riverbed of the lower reaches of the river.

Xiaolangdi reservoir is located in the middle reach of the Yellow River, 130 km below Sanmenxia reservoir. The drainage area of the reservoir is about 694,000 km², about 92.3% of the total basin. The design objectives are mainly flood control, ice flow flood control, sediment reduction, water supply, irrigation, and power generation. With a total capacity of 12.65 billion cubic meters and a live storage of 5.1 billion cubic meters and a population of 200,000, the reservoir enables the flood prevention standard to be improved from one flood in 60 years to one in 1,000 years. With joint operation, the reservoir plays an important role in sediment trapping and the formation of the lower river channel. During 2002–2005, four water and sediment regulation investigations were carried out and about 0.3 billion tons of sediment have been transported into the sea.

Xiaolangdi reservoir's role in harnessing of the Yellow River

The main objectives of the project are to:

1. Control flooding and ice jamming in the lower reaches in the Yellow River Basin to protect people and infrastructure
2. Control siltation in the 800-km downstream channel and prevent further aggradation so that levee raising can be delayed or controlled by 20 years
3. Provide water for assured irrigation for two million hectares and water supply to the cities and industries
4. Generate hydropower, replacing thermal generation in Henan Province and the Central China Power Grid

The project generates enormous benefits as follows:

1. Flood control measures significantly reduce the risk of major floods, normal annual floods, and ice-jam-related breaches of river embankments. The benefits are in terms of damage reduction to agriculture, urban, and industrial areas.

Some 100 million people benefit from protection of large floods and about three million people from annual and frequent floods (one in 5 years or less).

2. Benefits from sediment control are also significant, consisting mainly from reduced expenditure for embankment raising and maintenance.
3. Power benefits from peak power generation and avoiding the building of alternative thermal generation using gas turbines or other sources.
4. Irrigation and water supply benefits raising the yield of crops (mainly grain) to about double their present production and intensity of cropping over some 2 million hectares. More water is thereby made available to cities such as Qingdao and avoiding industrial output.

Flood control

Xiaolangdi Reservoir is located in the outlet of the last gorge of the middle yellow River below which is the large plain formed by the Yellow River, Huahe River, and Haihe. The significance of the Xiaolangdi site is that it controls over 90% of the basin. With the reservoirs Longyangxia, Liujiaxia, Daliushu, Qikou, Guxian, and Sanmenxia, the integrated planning of the Yellow River management with the formation of seven key engineering works.

The main objective of flood and ice control is based on the convenient geographical position and large reservoir capacity.

After the Xiaolangdi reservoir is operational, it cannot only store floods from reaches between Sanmenxia and Xiaolangdi but also reaches from Sanmenxia. When the reservoir is operated jointly with Sanmenxia, Guxian, and Luhun reservoirs, if a flood of frequency of one in 1,000 years occurs, the discharge at the Huayuankou gauging station won't exceed the present designed flood control standard of 22,000 m³/s; if a flood of frequency one in 100 years occurs, Dongping lake water detention area is unnecessary to be put into operation and the discharge at Huayuankou can be controlled below 15,000 m³/s.

Xiaolangdi reservoir mitigates the burden of the Sanmenxia reservoir. The chance of storing water in Sanmenxia reservoir can be reduced, which significantly slows the sedimentation in the reach to Tongguan.

The Xiaolangdi reservoir has significantly improved the flood control situation in the lower Yellow River, and the flood discharge ability is greatly improved in the Shandong reach. Since the reservoir was put into use, four water and sediment regulations have been carried out. During 2002–2004, large amounts of scoured sediment were transported to the sea. As a consequence, sedimentation has been improved and the flood discharge ability of the river improved. Water levels in the rising reach were 0.49–1.00 with discharges of 2,000 m³/s in 2004, lower than in 2002. Bank-full discharges improve from less than 2,000 m³/s to more than 3,000 m³/s. In 2003, six floods occurred in the Yellow River. In the rivers Jinghe, Weihe, Liluo, and Qin but with the joint regulation of Xiaolangdi, Sanmenxia, Luhun, and Guxian, the flood peaks are reduced, and the peak discharge at the Huayuankou gauging station is controlled at about 2,500 m³/s. Large areas of the floodplain were prevented from inundation and flood prevention pressure was relatively less.

Sediment reduction

Xiaolangdi was designed with the function of sediment trapping and can trap some ten billion tons of sediment. The period of sediment trapping can last 20 years. About one third of sediment of the Yellow River (0.5 billion tons) was silted annually in the reservoir. If combining other measures such as warping in Xiaobeiganliu (the main stream from Yumenkou to Tongguan), the period may even last longer.

With long-term water and soil conservation measures such as returning fields into forests and planting trees and grasses in the loess plateau which is the most serious area of soil erosion, a complete sediment disposal plan with different stages and different focuses has been formed. To store water in the reservoir before 2020 will be an effective way to reduce sediment in the lower river channel. The reservoir releases clear water to scour the lower river channel, and the sediment scoured in Baihe-Lijin reached as much as 0.172 billion cubic meters in the year 2000–2001 or about 0.5 billion tons.

Water supply

With 4 billion cubic meters or so capacity for flood control, the Xiaolangdi reservoir plays the role of flood control in the flood season and regulates runoff in the low flow or dry weather season. On average, there will be 2.6 billion cubic meters more water for water supply. This will ensure supply to cities and villages along the Yellow River and Central Plains Oilfield and Victory Oilfield and provide water to Shandong province in the dry weather seasons. In addition it will enable to transfer water to Tianjin of which ten times of the previous amount has now been transferred from the Yellow River, amounting to about 0.9 billion cubic meters each time.

Power generation

The installed capacity of the reservoir is 1.8 million kw, and the designed annual power generation is of the order of 5.1 billion kw.h. In 2004 the water efficiency was further improved. The water-discarding ration was reduced to 13.5%, and annual power generation was up to 5 billion kw.h. From 2001–2004, the total power generated was over 14.5 billion kw.h. The reservoir also plays an important role in the Human electricity network.

Three water and sediment regulation experiments

Several water and sediment regulations have been carried out with joint operation of the Xiaolangdi reservoir as well as other reservoirs in the mainstream and branches of the Yellow River. The so-called water and sediment regulation will form a suitable relation between water and sediment so that sediment discharging efficiency can be optimized and more sediment may be transported into the sea with less water.

The first water and sediment regulation was carried out in 2002. Clear water was discharged from the reservoir, with designed discharge and sediment content, and some 66.4 million tons of sediment scoured into the sea. In 2003, a larger-scale water and sediment regulation was carried out.

With joint operation of Sanmenxia, Xiaolangdi, Guxian, and Luhun, together four reservoirs, muddy water discharged from Xiaolangdi reservoir and clean water from the Yiluo River joined suitably at the Huayuankou gauging station to form a flood with discharge of about 2,600 m³/s and sediment content about 30 kg/m³ so that

the optimum water and sediment relation can be realized. Within 12 days, approximately 0.12 billion tons of sediment was transported into the sea. Included in this sediment released from the reservoir is 74.0 million tons, and scoured sediment from the river channel amounts to some 45.6 million tons. During 3 years of experiments, water stored in Xiaolangdi reservoir was fully utilized and the sedimentation situation of the reservoir was improved. The river bed of the lower reach was scoured, and the rules of density, flow, etc., were further realized. In 2005, water and sediment regulation began as routine.

Conclusions

After Xiaolengdi reservoir was first put into use, it has subsequently played a significant role in flood control, ice flood control, sediment reduction, irrigation and power generation, etc. However, at present the planned Guxian reservoir is still under demonstration. Due to

the limited capacity and the rising elevation of Tongguan, Sanmenxia reservoir's operation mode is completely discharged for most of the time. The regulating capacity of the present reservoirs is still limited. Though the sedimentation situation of the lower Yellow River has improved, the secondary suspended river phenomenon is still very serious. In addition, there is still a large area without controlling engineering works in the lower reach. With continuous dry years, the frequency of large floods threatens the safety of the people living in the floodplain; the flood control situation should be taken seriously.
